The first volume contains a collection of the ancient references to the life and deeds of Asclepius, his cult, images and temples; the second comprises an analysis of the material assembled in volume one. The material is restricted to written evidence and does not consider the cultural evidence portrayed in sculpture and painting and on coins. Although the work aims at an insight into the essence of Asclepius and of the cult attached to him, it also intends to provide a commentary on the whole ancient testimony on Asclepius preserved in books and on stone. The text is well written and printed on good paper, with a good type. This scholarly treatise should be in all medical-history collections, both public and private.

Surgical Treatment of the Motor-Skeletal System Part One *Deformities, paralytic disorders, muscles, tendons, bursae, new growths, bones, joints, amputations*. 4°, cloth, 641 pp., with 520 illustrations and a color plate. Part Two *Fractures, dislocations, sprains, muscle and tendon injuries, birth injuries, military surgery*. 4°, cloth, 639 pp., with 543 illustrations. Supervising editor, Frederic W. Bancroft, M.D. Associate editor, Clay R. Murray, M.D. Philadelphia: J. B. Lippincott Company, 1945. \$20.00.

This, as its name implies, is a two-volume treatise on the surgical treatment of orthopedic disabilities. It has been edited most ably by Drs. Bancroft and Murray, of Columbia University College of Physicians and Surgeons. The con-

MILITARY SURGERY IN WORLD WAR II*

A Backward Glance and a Forward Look

MICHAEL E. DeBAKEY, M.D.†

NEW ORLEANS, LOUISIANA

A DISTINGUISHED alumnus of Harvard University, Walter Lippmann, recently quoted what he identified only as the remark of a discouraged man: the lesson of history is that the lesson of history is never learned. Certainly, that statement holds for almost every phase of military surgery. We did not profit by the experience of World War I, much less that of previous wars, and in many respects it took us a discouragingly long time to comprehend the lessons that took form during World War II.

Perhaps the chief reason for our early difficulties in World War II is that we had not read the official British and American histories of World War I. Major General Philip Mitchiner, in 1944, confessed that sin of omission for the Royal Army Medical Corps, and it is open to question whether some American medical officers even now know that the histories exist. A partial explanation may be that the American history was published too long after the war had ended. By the time the first volume appeared, American physicians had dismissed from their minds most of the recollections of World War I, and in 1929, when the last volume appeared, a second world war still seemed inconceivable.

Trench foot, which is a responsibility of Command quite as much as of the Medical Corps, is an excellent illustration of a lesson that we should have learned and did not. In the spring of 1943 the campaign in the Aleutians produced several hundred cases of what was termed "immersion foot." In the following winter there were several thousand cases of what was unmistakably trench foot among the Fifth Army components fighting on the Italian Front. In the winter of 1944-1945 there were some 50,000 cases among the American forces fighting on the Western Front, the first concentrations of cases occurring during the critical days of the Battle of the Ardennes Bulge. The great majority of those cases, it is fair to say, should never have

occurred. Larrey, Napoleon's surgeon, had written a classic description of the condition, which contained many a useful warning, well over a century before. Trench foot, under other names, was reported in the Crimean, the Russo-Japanese and the Balkan wars. The British armies in Flanders and on the Somme had learned about it the hard way in World War I and had remembered the lesson through the years; trench foot was no problem among the British troops in World War II. We ourselves had had the experience in the Aleutians to prepare us for Italy, and that in Italy to prepare us for the Western Front. In fact, in the summer of 1944 the débacle of the coming winter on that front was clearly prophesied by the Surgeon General's Office. It is small consolation to reflect that had the Pacific War required the invasion of Japan and Manchuria, where the conditions of winter fighting in Europe would have been duplicated, the incidence of trench foot would probably have been minimal for prophylaxis had been most carefully planned on both Command and Medical Corps levels.

Other illustrations can be mentioned only briefly. If, for instance, we had read of or had remembered the many and futile attempts in World War I to sterilize wounds by means of antiseptics, we should have known better than to put our faith in any extraneous substances, including the sulfonamides on which we leaned so heavily in the early days of World War II. If we had read nothing more than the report of the Inter-Allied Surgical Conference in Paris in 1917, we should have known and could have put into immediate practice all the essential principles in the management of war wounds that were finally learned after many months of costly experience in World War II.

Medicomilitary lessons, like strictly professional lessons, were also learned the hard way. The possibilities of body armor, for example, were discussed in considerable detail in the history of the American Medical Department in World War I. Protective devices were adopted in World War II by the Air Force, with considerable savings in deaths and

†Associate professor of surgery, Tulane University of Louisiana School of Medicine.

Skin Diseases, Nutrition and Metabolism By Erich Urbach, M.D., associate in dermatology, University of Pennsylvania School of Medicine, and chief of Department of Allergy, Jewish Hospital, Philadelphia. With the collaboration of Edward B. LeWin, M.D., associate in medicine, Jewish Hospital, Philadelphia. 8°, cloth, 634 pp., with 266 illustrations and 112 tables. New York: Grune and Stratton, 1946. \$10.00.

In this new book Dr Urbach stresses the use of dietary measures in the treatment of dermatoses. The text is divided into five parts: the influence of nutrition on the physiology of the skin, nutritional causes of dermatoses, including food allergy, the influence of diseases of the gastrointestinal tract, liver and pancreas on the skin, and nutritional therapy of skin diseases followed by a series of nutritional tables. A bibliography of one thousand three hundred and seven references is carried throughout the text as footnotes to the various chapters. Indexes of authors and subjects conclude the volume. This book should be in the reference collections of all medical libraries and should prove of value to allergists and dermatologists.

Alcohol Reaction at Yale By Ernest Gordon. 8°, paper, 87 pp. Francetown, New Hampshire: The Alcohol Information Press, 1946. Single copy, \$1.00, ten copies, \$6.00, postpaid.

This pamphlet constitutes an argument for prohibition.

NOTICES

ANNOUNCEMENT

Dr Raymond Gelfman announces the opening of his office for the practice of internal medicine at 10 Chestnut Street, Springfield.

FOOD AND HEALTH CONFERENCE

On March 20 the North Metropolitan District of the Massachusetts Department of Public Health will present a Food and Health Conference in the auditorium of the Public Works Building, 100 Nashua Street, Boston. The morning session will be held from 10:00 to 12:00, and the afternoon session from 2:00 to 4:00.

This meeting has been planned for health workers in the district. Discussions on the psychiatric problems in dietetics, recent developments in nutrition research, techniques for teaching nutrition, sanitation and visual aids have been planned, and there will be four exhibits. All are urged to attend this meeting and learn latest information regarding nutrition and new techniques for teaching.

MASSACHUSETTS PHYSICIANS' ART ASSOCIATION

The Massachusetts Physicians' Art Association has been established to encourage and stimulate the interest of physicians in drawing, painting, sculpture and photography. Any member of the Massachusetts Medical Society is eligible to join the association and may do so by sending in the annual dues (\$2.00) to the treasurer, Dr Robert W. Buck, 5 Bay State Road, Boston. This sum is to cover the cost of notices of meetings and the expenses of the yearly exhibition, which will be held this year at the Hotel Statler in conjunction with the annual meeting of the Massachusetts Medical Society, May 20 to 22. It is planned to hold meetings in Boston each month in the winter, with informal talks or classes for those who wish to draw or paint. Notice of the meeting in March will be sent on receipt of the dues. Additional information, if desired, may be obtained from the secretary, Dr Somers H. Sturges, Massachusetts General Hospital, Boston 14.

GREATER BOSTON MEDICAL SOCIETY

A meeting of the Greater Boston Medical Society will be held in the auditorium of the Beth Israel Hospital on Tuesday, March 4, at 8:15 p.m. Dr Murray J. Shear, chairman of the Chemotherapy Section, National Cancer Institute, will speak on the subject "The Chemotherapy of Cancer." Drs. William Dameshek, Saul Hertz, Ira Nathanson and Arnold Seligman will participate in the discussion.

WINTHROP COMMUNITY HOSPITAL

The regular monthly meeting of the staff of the Winthrop Community Hospital will be held on Thursday, March 27, at 9 p.m. at the hospital. Dr Howard A. Hoffman will speak on the subject "Urologic Problems in General Practice."

NEW ENGLAND HEALTH INSTITUTE

The New England Health Institute will be held at the University of New Hampshire, Durham, New Hampshire, on June 16, 17 and 18. This will be the first meeting since the war. A comprehensive program is being arranged, and the speakers will include many of the outstanding health and education authorities in the country. Special attention is being given to the timing of the different sections so that similar subjects will not overlap.

The facilities of the University will be at the disposal of those attending. Rooms will cost from \$1.00 to \$1.50 per day, special provisions being made for married couples. The school dormitories will be conducted on a hotel basis. Meals will be served in the dining halls at an approximate cost of \$1.50 to \$1.75 per day. There will be a banquet on Tuesday evening.

Since a large attendance is expected, all who plan to participate should register early. More detailed information will appear in a later issue of the *Journal*.

THIRD AMERICAN CONGRESS ON OBSTETRICS AND GYNECOLOGY

The Third American Congress on Obstetrics and Gynecology will be held September 8 to 12, 1947, in St. Louis. The program will feature general sessions for all groups making up the Congress, as well as small individual group meetings and round-table discussions. The morning sessions will be panel-type presentations of the following subjects: anesthesia and analgesia, cancer, and cesarean section. The afternoon meetings of the medical section of the Congress will consider psychosomatic aspects of pregnancy, pregnancy complicating cardiac disease, diabetes and tuberculosis, recent advances in endocrinology. Round-table discussions from four to five o'clock daily will consider such topics as etiology of abortion, asphyxia, fibroids, prolonged labor, infertility, early ambulation, adolescence, treatment of abortion, genital relaxation, ovulation, the menopause, the cystic ovary, uterine bleeding, nutrition in pregnancy, gynecologic pathology, endometriosis and erythroblastosis.

INTERNATIONAL CANCER RESEARCH CONGRESS

The Fourth International Cancer Research Congress will be held in St. Louis on September 2 to 7. The Union Internationale contre le Cancer having accepted the invitation of the American Association for Cancer Research, the congress will be held under the joint auspices of these two organizations, with Dr E. V. Cowdry, professor of anatomy, Washington University School of Medicine, and director of research at the Barnard Free Skin and Cancer Hospital, serving as president. The State Department in Washington has approved of the congress, and official invitations will soon be sent to all foreign governments that are to be asked to send delegates.

Initial steps in the organization of the congress have already been completed. In addition to Dr Cowdry, Dr J. Godard, president of the Union Internationale contre le Cancer, and Dr W. U. Gardner, president of the American Association of Cancer Research, will serve as *ex-officio* members of the Executive Committee. The following personnel have accepted committee chairmanships: A. N. Arneson, St. Louis—Local Arrangements; S. Bayne-Jones, New Haven—Finance; C. W. Larimore, New York City—Exhibits; L. A. Scheele, Bethesda, Maryland—Governmental Liaison; M. G. Seelig, St. Louis—Publicity, and Shields Warren, Boston—Program.

Headquarters will be at the Hotel Jefferson, St. Louis, where some 300 rooms will be available for guests. In addition, other nearby St. Louis hotels have signified a willingness to make reservations on advance notification by those contemplating attendance at the congress.

(Notices continued on page xv)

figures are not available, I am convinced that the salvage in morbidity was even greater

THE BACKGROUND OF MILITARY SURGERY

Before discussion of how these improvements were brought about in World War II, it is well to consider the background against which military surgery must be done. The surgery of a modern war has been aptly defined as the surgery of trauma in epidemic proportions. The demand is so enormous that it can be met only by a closely co-ordinated, well integrated medical organization prepared to operate promptly, efficiently and simultaneously under widely varying conditions and in all parts of the world. The organization must be highly mobile, so that it can move with the battle, otherwise it will lose its usefulness. It must function without interfering with the battle, the first objective is to get on with the fighting, and to fail in it or to impede it would not be to the best interests of the wounded, either individually or en masse.

The medical organization must operate long lines of evacuation from the front, where injury occurs and first-aid measures are carried out, to the rear, where definitive treatment is given, and thence to the homeland, where final therapeutic measures are applied. At the same time it must be prepared to treat well toward the front lines both men who are so lightly wounded that they can be promptly returned to duty and those who are so seriously wounded that they cannot be moved farther without treatment, or who require without delay operations of such a character as to prohibit transport immediately afterward. The whole process of evacuation, in fact, must be conducted on the basis of the transportability of the patient, which is itself predicated on the character of the injury, the physiologic reaction of the patient and the therapeutic measures employed.

All the circumstances of war surgery thus do violence to civilian concepts of traumatic surgery. The equality of organizational and professional management is the first basic difference. The second is the time lag introduced by the military necessity of evacuation. The third is the necessity for constant movement of the wounded man, and the fourth — treatment by a number of different surgeons at different places instead of by a single surgeon in one place — is inherent in the third. These are all undesirable factors, and on the surface they seem to militate against good surgical care. Indeed, when the over-all circumstances of warfare are added to them, they appear to make ideal surgical treatment impossible. Yet this was not true in the war we have just finished fighting, nor need it ever be true. Short cuts and measures of expediency are frequently necessary in military surgery, but compromises with surgical adequacy are not.

A number of factors, some inherent in the military circumstances and others created by proper concepts

and derivative planning, overcame the obstacles to ideal surgery in World War II. The first of these was what might be termed the standardized pattern of trauma and of physiologic response to it. Most of the diagnostic confusions of civilian medicine do not exist in military surgery, although, naturally, I do not mean to imply that serious diagnostic problems are not involved. On the other hand, whether a wound is in the extremities or in the abdomen or chest, or is caused by a high explosive, a land mine or a jeep, the pattern assumes the same general characteristics, the physiologic response, whether actual or potential, can be assumed to be similar, and the therapy required, resuscitative as well as

FIGURE 3 Percentage of Expected Deaths (Based on World War I Mortality Rates) Avoided in World War II

surgical, follows the same general lines. Furthermore, the United States Army consisted on the whole of a selected group of men, in the best years of their lives, in whom physical defects and chronic and degenerative diseases had been excluded by preliminary screening.

At least two planned factors also compensated for the unfavorable background of military surgery. The first was the principle of standardization or, as some might choose to term it, of regimentation. The framework into which the wounded man and the medical officer were alike required to fit was frankly rigid. But within the framework individual initiative was both permitted and encouraged, the ability and skill of the experienced surgeon were stimulated, and the less experienced surgeon was provided with training and guidance. As always, a general uniformity of technical procedure was regarded as essential, for reasons of safety, simplification and expedition, to make mass instruction of the medical personnel feasible and to permit standardization of basic equipment. I might interpolate that the directives and other means by which information and advice were disseminated were based on actual experience and represented the composite, carefully

wounds, by the end of 1943. On the basis of this experience, small though it was, and of several intensive studies on the lethality of weapons, it should have been apparent that great benefits might be derived from further developments in this field. Available statistics suggested that their adoption might reasonably be expected to reduce the number of men killed in action by 12 per cent and of those

obstacle to objectivity as prejudice or indifference. In the second place, a much longer time will be required to analyze all the medical data statistically and qualitatively. Representative samples, however, permit definitive conclusions and make clear the salvage that occurred in World War II, both absolutely and as compared with that in previous wars, in spite of our failure to learn the lessons of those wars.

From the Peninsular War, which began in 1808, through World War I, a period of more than a century, the proportion of men dying of battle wounds was almost halved (Fig 1). In World War II, which occurred only twenty-five years later, the proportion of men dying of battle wounds was again almost halved, although the number of wounded exceeded those in any previous war so recorded that estimates are possible. The absolute magnitude of these gains is not in any way invalidated by the unhappy realization that had we learned our lessons earlier, the salvage might have been still greater.

The case fatality rates of World War II, when examined from the standpoint of regional injuries, were from 25 to 50 per cent lower than those of World War I, which themselves showed a considerable reduction over comparable rates in the Civil War (Fig 2). For the sites that were potentially the most fatal — that is, the head, chest and

FIGURE 1 Mortality of Wounded in Various Wars

wounded in action by 8 per cent, but the Pacific War ended before body armor was in use on any front.

Convalescent camps, which were authorized for each hospital group in May, 1918, formed no part of the original planning for World War II and were provided, as in World War I, only after experience had shown that they were needed. Field hospitals for major surgical procedures were not planned in World War I for nontransportable patients who required prompt life-saving surgery, but were developed when the need became evident. It is ironic that in World War II the same evolution was necessary, although little reflection seems needed to make it plain that many of the injuries responsible for the greatest loss of life must be treated at this level if salvage is to be accomplished. At the end of the war, the field hospital still did not have tables of organization and equipment and, in the minds of administrative personnel, was still not fully accepted for the purposes it was serving, although it was the only available unit that could have been modified and made sufficiently flexible to meet them.

Whether a valid appraisal of the surgery in World War II is possible at this time is seriously doubtful. In the first place, we are still much too close to what has happened to permit comments that would be entirely objective, too many considerations, many of which have nothing to do with medicine, are likely to color our thinking, and under the circumstances overenthusiasm would be quite as much an

FIGURE 2 Mortality in Various Wars according to Location of Wound

abdomen — the rates in World War II were a half to two thirds below those in World War I.

Finally, to examine the gross statistics from still another standpoint, had the death rates after wounding that obtained in World War I been duplicated, almost 22,000 more deaths would probably have occurred in World War II (Fig 3). This is a total salvage of 45 per cent, and on a relative basis the calculated savings equal or exceed 35 per cent for every region of the body. Although comparable

to the realities. At the end of World War I specialized military practice ceased to exist with the rapid demobilization of the Medical Corps and, for all practical purposes, remained nonexistent during the interval between the wars.

Many of the difficulties that attended the effective utilization of specialists in World War I were avoided in World War II. Within three months of our entrance into the war there was established in the Office of the Surgeon General a Professional Consultants Division of full-time officers, with ranks eventually appropriate to their duties, although the administrative authority with which they were endowed was never fully adequate for their responsibilities. I need not repeat that the Surgical Consultants Division was headed by Brigadier General Fred W. Rankin, but I do want to pause to pay tribute to the native ability, the trained competence, the hard common sense and the uncompromising and unswerving honesty of purpose with which he carried out his duties, with the single-minded objective of providing for American soldiers the best surgical care any army has ever had.

As the war progressed, consultants in the major specialties, and usually in the subspecialties, were eventually appointed in every service command in the Zone of the Interior and in the Mediterranean and European theaters. The system, most regrettably, was never fully implemented in the Pacific, partly because of shortages of personnel and partly because of the deliberate postponement of the major effort in that area until the conclusion of the war in Europe. These consultants were selected with the utmost care, on the basis of training, ability, accomplishments and professional eminence, as a Boston audience need not be reminded, since the chief consultant for the Mediterranean Theater was Colonel Edward D. Churchill and the chief consultant for the European Theater was Brigadier General Elliott C. Cutler. From the medical standpoint, these were the important theaters, and Colonel Churchill and General Cutler exemplified to the highest degree the value of the consultant system and the possibilities of accomplishment within it.

The function of the surgical consultants was rather loosely defined as the promotion of the highest standards of medical practice within their areas of responsibility. They fulfilled it not primarily by the development of policies, but by the effective utilization and the continuing assessment and reassessment of specialized surgical personnel. When qualified personnel were properly assigned, policies developed of themselves. These surgeons were well trained men, many of them with long experience in civil life. Their concepts of surgery were correct. They were thoughtful as well as technically able. Their minds were open, and they realized the importance of changing their original convictions in the light of altering developments and cumulative experience.

They were widely distributed and traveled widely, so that their influence spread in ever-widening circles. It is no paradox to say that although most of them did no surgery and treated no patients in the course of the whole war, they were responsible for incalculable savings of life and limb.

SURGICAL ADVANCES IN WORLD WAR II

No major revolutionary changes in surgical practice were introduced during World War II. On the other hand, because of the enormous, concentrated surgical experience, principles were rapidly established — and are now being applied in civilian practice — that in the ordinary course of events would have taken years to establish. Furthermore, as the war progressed, there was an extraordinary appreciation, as well as a remarkably intelligent application, of fundamental principles so adapted as to meet the exigencies of military surgery. We were slow to learn some lessons and slow, perhaps, to utilize our experiences, but eventually certain concepts in the various fields of surgical endeavor became more clearly defined and their technical application became more general, with progressive improvement in mortality and morbidity rates.

The major advance, which underlay the progressive improvement in results accomplished as the war progressed, was the concept of phased wound management developed by Colonel Churchill in the early days of the Mediterranean fighting. This principle recognized the factors in the military environment that precluded ideal surgical practice and compensated for them by a rational timing of surgical measures to conform, in general, with the tactical necessities of the military situation. Its three phases were as follows: initial wound surgery, a function of advanced hospitals in the Army area, which was concerned with surgical procedures designed to save life and prevent or eradicate wound infection, reparative surgery, a responsibility of general hospitals in the Zone of Communications, which was concerned with procedures designed to shorten the period of wound healing, restore early function and minimize ultimate disability, and reconstructive surgery, a function of general hospitals in the Zone of the Interior, which was concerned with the correction of deformities and with rehabilitation in general.

The first and second phases of this plan took advantage of established principles of wound healing. From a military standpoint the entire concept was based on the fact that shortly after the first phase most patients, except those with penetrating wounds of the chest and abdomen, are safely transportable, whereas immediately after the second phase they become nontransportable for periods varying from a few weeks in cases of soft-part wound to several weeks in cases of fracture. By proper co-ordination of the three phases of this plan in time and space,

arrived at conclusions of many surgeons rather than the whims and practices of a single surgeon or one group of surgeons

A second compensatory factor was the precise definition of the function of each echelon in the chain of evacuation, from the first aid given on the battlefield by medical corpsmen to the reparative surgery performed in the general hospital at the base. Each procedure was timed and graded in relation to the whole picture, including the tactical situation, the particular point in the chain of evacuation and the wounded man's own status. Hospitals were designed and equipped for surgery of varying degrees of urgency and magnitude, with due consideration of the necessary duration and other requirements of postoperative care, and were strategically placed with reference to those considerations. Professional personnel were distributed in accordance with the function of the installation and the type of surgery to be performed. It is to the credit of a profession of individualists that almost every man submitted to these medicomilitary disciplines, recognized their necessity and justice, and confined himself to the job he was assigned to do where, when and as he was directed to do it.

Regimentation was based on fundamentally sound principles. The directives provided, for instance, that except for maxillofacial and cranial injuries, all wounds must be left unsutured after débridement, that all amputation stumps must be left unsutured, that transportation casts must be split or bivalved as soon as the plaster was dry and that injuries of the large bowel must be treated by exteriorization. Undoubtedly the transgression of any of these directives would have been practical and safe in numerous selected cases, but not much reflection is needed to make clear the folly of permitting the privilege of selection under combat conditions to thousands of surgeons who had been trained under varying schools of surgical thought and who were of varying degrees of ability and experience.

It was also necessary to view certain elective procedures in the cold light of military realism. What is good practice in civilian surgery is not necessarily the best practice, or even good practice, in military surgery. It was estimated, for example, that over a two-year period, 425,000 hospital days (approximately 1192 man years) were saved, and a corresponding amount of manpower time was made available, by the limitation of the treatment of pilonidal cyst and sinus to simple incision and drainage, or by the withholding of surgery altogether. Likewise, large savings were made and a great many difficulties circumvented by the adoption of conservative policies in the management of hydrocele, internal derangements of the knee and herniated nucleus pulposus.

Perhaps the most striking illustration of the necessity of detailed planning and of the value of uniformity of organization is supplied by the processing

of injured men on their return to the Zone of the Interior. For a period of some six months casualties from overseas were received at the ports at the rate of about 1000 a day. For a few months they numbered almost 2000 a day, and a large ship, such as the *Queen Mary*, might transport as many as 3000 at a time. Yet day after day, within an average of seventy-two hours of their arrival, most of the injured men were on their way by train or plane to the general hospitals selected as appropriate for them after assessment of their specialized needs at receiving hospitals on the coasts, procurement of authorized bed space from Washington and as much consideration as possible of the proximity to their homes of the hospitals to which they were sent. A triage of such monumental proportions would have been a remarkable achievement no matter how it was accomplished. That it was carried out with minimal errors in assignment and with no accidents of any consequence is as much a tribute to the planning of this special operation as it is clear-cut proof of the necessity for standardization of procedure.

The competent performance of the surgical personnel who participated in World War II undoubtedly had more to do with the surgical results achieved than any other single factor. That performance was made possible, in turn, by the increased availability of such personnel, in comparison with World War I, and by proper assignment.

The principles of specialization, as the term is understood today, had scarcely developed when the United States entered World War I. The Surgeon General, however, showed his awareness of the trend and took official cognizance of it by the appointment of a civilian specialist to advise him concerning surgery and the surgical specialties. This officer, who entered the Army with the rank of major and who served only part time, was responsible for the later selection of an advisory board, quite loosely organized and appointed on a geographic as well as a professional basis. At the same time, consultants in major specialties and subspecialties were appointed to overseas hospitals and units.

Although these concepts represented a real advance in military surgery, the theory of specialization was never fully translated into practice during World War I. The original development was undirected and unwieldy, and for a time the basic specialties of medicine and surgery were almost submerged by the independent mushroom growth of the subspecialties. Furthermore, the criteria of classification of specialists were elementary — they could hardly have been otherwise, for the modern system of residencies was practically unknown and the first of the qualifying boards did not come into existence until 1916. As a result, the applicant for a commission was graded chiefly on the basis of his personal statement of his qualifications and training, which, as might have been anticipated, sometimes bore little resemblance

valuable work, to which I am glad to pay my own personal tribute, is undoubtedly familiar to all. Nonetheless, from the standpoint of military surgery, it never completely succeeded in accomplishing its objectives, because of the barrier between military surgeons and civilian investigators that was never completely crossed on either side. Liaison existed between the Army and the various subcommittees of the National Research Council, it is true. Data from the field were supplied to the civilian investigators within the limits permitted by security regulations. Security regulations, unfortunately, were too often interpreted and applied with extreme severity, and medical documents that would have been of the greatest usefulness to research workers were classified far beyond the limits required by military security. Reports were made to appropriate subcommittees by occasional surgeons returned from overseas, and an occasional observer from the Council made surveys in the field. But complete integration of ideas and purposes was almost never achieved — not through any fault of personnel or through any lack of desire, but because of the initial setup. The failure was fundamentally due to the artificial and fallacious concept that a military problem could be detached from its military background, solved as an abstract problem in a civilian laboratory by civilian investigators who had no contact with it at its point of origin, and handed back to the military surgeons, completely solved and accompanied by appropriate therapeutic recommendations. Working in their own airtight compartments, civilian investigators naturally could not develop a true concept of the background of military surgery, which differs in many respects, as emphasized above, from civilian surgery. Nor could they ever fully understand the special necessities of military surgery or its special urgencies. It is extremely significant, and indicative of their medical competence, that the civilian investigators themselves realized these handicaps. In its final report in September, 1944, the Subcommittee on Surgical Infections and Burns recommended that thereafter such projects be carried out by qualified groups in the Services and that future civilian projects be limited to laboratory and other studies that could not be conveniently carried out in military hospitals.

The slow development of an optimum method for the treatment of burns is an illustration of the lack of integration of research studies and military surgery. Authoritative pronouncements were badly needed. In 1939, at the beginning of the war, tannic acid was the most widely used of all local agents. It was not satisfactory, but no other of the multiple methods then in use was considered any better. In October, 1942 the Subcommittee on Burns of the Division of Medical Sciences of the National Research Council, in response to a communication from the Surgeon General, recommended that the Army postpone further purchases of tannic acid

until additional information could be obtained. During the following month, in spite of a statement by the chairman early in the discussion that tannic acid jelly should not be used for either first-aid or definitive therapy, the tanning (eschar) treatment was recommended by the subcommittee for certain rather large categories of burns, and it was not until July, 1943, that the discontinuance of all escharotics was recommended and the substitute recommendation was made that first-aid measures consist only of the application of an oily, nonadherent agent, such as petrolatum.

By the time this conclusion was reached, the Surgical Consultants Division, on the basis of clinical experience in the North African Theater of Operations, which had clearly proved the ineffectiveness and actual danger of the eschar treatment, already had in preparation and on its slow way through channels a circular letter forbidding the use of any tanning agents and recommending simple pressure dressings, whose effectiveness had first been mass tested in the Coconut Grove fire in November 1942.

The evolution of recommendations concerning the use of chemotherapeutic agents was similarly slow. In July, 1940, the Subcommittee on Surgical Infections, in collaboration with the Committee on Therapeutics and Other Agents, had recommended the oral prophylactic administration of some sulfonamide drug as soon as possible after injury, as a means of preventing infection. It was reluctant to advise the local use of these drugs because, in spite of lay and professional enthusiasm for the practice, no adequate data were available to justify such treatment. Eventually, however, in response to an urgent request from the Surgeons General of the Army and Navy for a ruling, local chemotherapy was recommended. As a result of these recommendations, the individual first-aid kit was provided with sulfonamide tablets for oral use and with dusting powder for use in wounds.

When funds became available to the National Research Council, controlled studies were instigated under its auspices and were carried out by competent investigators in civilian hospitals in more than 2000 cases of traumatic wounds. The conclusion was reached, after the first 1000 cases had been analyzed, that when predisposing factors exist for the development of infection in accidental wounds, the use of chemotherapeutic agents in any combination and by any route does not prevent its development, although systemic therapy is probably of value in preventing invasive sepsis. In its final report, in September, 1944, this conclusion was retained, but the subcommittee declined, because of the differing conditions in civilian casualties and battle casualties, to institute comparisons, nor would it make any recommendations for the use or the omission of bacteriostatic drugs as prophylactic agents in the prevention of local infection in war wounds.

a close approach — perhaps the closest approach possible — to ideal methods of wound management was achieved within the limits of a military setting.

It proved possible to apply this principle of phased surgery to virtually every type of wound. Colonel Churchill himself admirably explained its application to thoracic surgery in World War II, in which, as he noted, the lung rather than the pleural space had become the focus of medical attention. In this type of surgery, he continued, two phases had to be recognized: physiologic disturbances and infection. The former required immediate correction in the most forward installation possible, sometimes by surgical measures; infection could occasionally be eliminated at the same time, but only incidentally. In general, the proper time to manage infection was within three days to six weeks after injury, and the place to correct it was an installation to the rear.

The phased management of abdominal injuries involving the large bowel required, in oversimplified terms, exteriorization of the injured segment in a forward installation, with subsequent closure of the colostomy in an installation in the rear. The phased management of fractures implied débridement of the wound and immobilization for transportation purposes in a forward installation, with later precise reduction and wound closure in a rear installation. Peripheral-nerve injuries, according to this principle, were débrided at initial surgery and sutured within an optimum period after delayed wound closure either overseas or in the Zone of the Interior, usually depending on the availability of transportation. Head and spinal-cord injuries and all other types were managed by similar temporal and spatial concepts.

Even the concept of resuscitation — ably developed in the Mediterranean Theater by Colonel Henry K. Beecher and based on a newer knowledge, largely provided by him and his associates — was phased, its objective being to present to the surgeon a patient who would be as favorable an operative risk as possible. Time does not permit a discussion of the important role played by this group of physicians in the delineation of the respective places of plasma and whole blood in resuscitation, in their bringing us back to sanity in the use of morphine (for which, they showed, a cigarette is sometimes an excellent substitute) and in anesthetic methods in wartime, a consideration of which would be peculiarly appropriate at this time and place.

A matter that statistics do not show and that deserves far more than the passing comment possible is the new approach to rehabilitation and reconstruction characteristic of surgery in World War II. Maxillofacial surgery achieved apparently impossible results, as did surgery of the hand. Programs of rehabilitation were designed for deaf and blind patients and for those who had lost limbs. The paraplegic program was not only a medical triumph and a shining illustration of the humanity with

which the science of surgery can be practiced but also a brilliant example of how co-operative medicine should be practiced.

RESEARCH ACTIVITIES IN WORLD WAR II

The research activities of World War II, brilliant as many of them were, furnish another excellent example of the lessons that we failed to learn from World War I. Important advances were made in various fields, but they were made late, after many hesitations and false starts, and in retrospect, it is easy to see how many opportunities were lost.

Significant information was obtained in World War I by research studies in overseas theaters concerning shock and hemorrhage, and by similar studies in this country regarding empyema. The data thus obtained were of great value in furthering knowledge of these subjects. Yet in spite of that experience, the policy in the early days of American participation in World War II discouraged clinical investigations in Army hospitals, research problems being referred to the National Research Council for investigation by civilian workers. The barrier thus set up was never completely crossed and was the chief reason for the delays and other inadequacies that attended the research problem throughout most of the war.

As the war progressed, the original policy discouraging research in Army installations was necessarily modified, and studies on special problems by small groups of investigators in the field proved feasible and valuable. Some of the studies carried out by members of the staff of the Massachusetts General Hospital and of the faculty of Harvard University provided information of the greatest value concerning the physiologic responses to shock, the bacteriology of wounds, the indications for transfusion in war surgery and, as mentioned above, the respective areas of usefulness of plasma and whole blood.

Isolated studies by individuals also frequently proved valuable, but many of them were invalidated by the lack of scientifically planned controls, and most represented an unnecessary waste of time, effort and personnel. During the war the Army Epidemiological Board had repeatedly shown what could be achieved by an organization prepared to function as soon as and wherever the necessity arose, and that board — and this is significant — functioned directly under the Secretary of War, with all the prestige and advantages of his authorization. It was not until August, 1945, when the great need and the great opportunity alike ceased to exist, that the Army Medical Research Board, with proper clinical representation, was finally set up in the Surgeon General's Office.

So much for the Army side of research during the war. Parallel, but seldom co-ordinated or integrated with it, was the effort of the Division of Medical Sciences of the National Research Council. Its

someness, an army in the field cannot operate, the inevitable result was a wastage of trained personnel that became increasingly acute as the war went on and that, had it lasted longer, might have been reflected in the care of the wounded. The problem was solved to some degree by the assignment of appropriate specialists to the points at which they could be most useful and by the concentration of patients with special types of injuries in centers equipped and staffed for their care, shortages of critical personnel, however, were always troublesome, and some of them were artificially created.

Such a situation must be avoided in the future. The medical profession is fully committed to the principle of specialization. It was employed in World War II far more extensively than in World War I because of two tendencies that had taken form in the interim between the wars. One comprised the efforts by civilian medical schools and hospitals to improve and standardize medical specialization by the provision of residencies and other facilities for postgraduate medical education. The other was the certification of specialists by the various qualifying boards. Neither of these tendencies, as already pointed out, existed prior to World War I, and it was the reservoir of specialists created between the wars that made possible the specialized and highly competent medical care given the wounded in World War II.

The philosophy of specialization in medical practice was based on too firm a foundation to have been overturned by a temporary, albeit catastrophic, interruption. The framework of its implementation, as a matter of fact, was actually strengthened by the experiences of the war and the performance of the specialists themselves. Specialization has now received legal recognition. It has been written into the laws governing the Veterans Administration, which, as a result, is providing for its charges medical care of a quality that it has never before provided. Equally strong efforts are now being made to continue specialization as an Army policy. The responsibility of the certifying boards and of teaching hospitals and medical schools, therefore, seems to be heavier than ever before, and the leaders in graduate educational endeavors must take full cognizance of the fact.

On the other hand, the policy of specialization must be applied with discretion and, so far as the Army is concerned, with understanding of military conditions. During World War II, as in every previous war, medical officers of the Regular Army necessarily assumed administrative positions. Their training had presumably fitted them better for those posts than it had for specialized professional service, whereas the civilian components of the Medical Corps were in most instances untrained for administrative posts, in which their specialized training and experience would have been wasted. Generally speaking, this is a sound policy. On the

other hand, the experience of World War II amply demonstrated the fallacy of the assumptions that a medical officer trained in a peacetime army was a priori fitted to assume a key administrative position during war and that a civilian surgeon necessarily lacked the qualities of leadership, judgment and vision required for it.

The degree of specialization to be required in the future Regular Army is difficult to determine at present. The size of the future military establishment is still undetermined, and specialization to be practiced effectively, requires concentrations of clinical material. The wisest plan may be for the Medical Corps of the Regular Army to provide the administrative structure and the general care of the troops, as well as the medicomilitary planning and training operations, leaving specialized hospital care to be supplied by a system of civilian consultants or of integrated federal medical service. The important consideration at present is not how the specialized care is to be supplied but that its necessity be recognized and, at the same time, the pitfall of too narrow specialization be avoided. It must also be constantly borne in mind that specialized practice emphasizes remedial medicine and that the Medical Department is a great deal more than a salvage service. The practice of preventive medicine and the planning for future operations are even more vital functions in war than in peace. In both its most valuable function is its advice to command.

The problem is not quite so simple, however, as this statement of policy implies. Other considerations are linked with purely military matters. During the war obvious shortages of personnel developed and certain specialists were always in critical supply, but the opinion was that once the war had ended, these difficulties would resolve themselves. They have not resolved themselves, nor does any thinking physician believe that they are likely to, at least under the system by which federal services are now operated.

It would be difficult to imagine a more wasteful and extravagant plan, for example, than the one on which hospitalization in this country is currently conducted. We have a system of private hospitals, of widely varying size and excellence. We also have, exactly as we had at the beginning of World War II, a fourfold, parallel system of federal hospitalization, including separate establishments for the Army, the Navy, the Veterans Administration and the Public Health Service, with confusion worse confounded by the maintenance of separate installations, sometimes only a few hundred yards apart, for the Air Forces and the Ground Forces. What this means in terms of wastage of material and equipment and money is perfectly obvious, what it means in terms of wastage of professional personnel particularly of specialized personnel, may not at first glance be so clear.

The reports from Pearl Harbor seemed to indicate that both local and systemic chemotherapy was highly effective in battle wounds. Undoubtedly much of the early reliance on chemotherapy was due to that experience. In the enthusiasm over the results, however, many Army and Navy surgeons, as well as many civilian surgeons, lost sight of the emphasis that these reports also placed on adequate surgery. As early as 1943, numerous reports from the Mediterranean Theater, later supplemented by reports from the European Theater, substantiated the conclusions of the National Research Council workers regarding the ineffectiveness of local chemotherapy in wound infections. Soon afterward, a directive was issued forbidding the local use of the sulfonamides, and they were no longer placed in the first-aid kit in any form.

It is pleasant to be able to report that most of these errors and hesitations were avoided in the study of penicillin and streptomycin. The investigations were set up by civilian investigators working under the National Research Council, and the projects, when they were fully operative, were taken over and carried on with great success by members of the Army Medical Corps specially assigned to and specially qualified for the work. The result was that when these agents were made generally available, the principles of usage had been clearly established and their limitations and risks had been equally clearly defined. Both projects represent the type of integrated civilian-military research that, unfortunately, so many other projects do not, and point the way to future planning for research in a similar emergency.

THE IMPLICATIONS OF MILITARY SURGERY IN THE POSTWAR WORLD

I hope that nothing that has been said will be interpreted to mean that the Medical Department of the United States Army did not do a competent job in World War II. It functioned superbly. No soldiers in any war ever had such care as was given to the American soldiers in the last war. If, on the other hand, what has been said seems to indicate that the formulation of policy of military surgery in World War II was a matter of evolution, it must be admitted that the implication is correct. The Medical Corps, like most other branches of the Army, entered on the emergency of World War II quite as unprepared as it had been at the outbreak of World War I. In large measure this was not the fault of the Surgeon General. For one thing, the American public, as always during years of peace, had shown no enthusiasm, but rather apathy and sometimes actual hostility, for planning for another war. Congress, the source of funds, had followed the same line.

Furthermore, and even more important, successive surgeons general of the Army, whatever their convictions, had little or no authority to act on them. In the midst of World War I, over the protests of

the Surgeon General then in office, the Medical Corps of the Army, previously an entity in its own right, had been placed under the Service of Supply (later the Army Service Forces) and by this move, in spite of his sole responsibility for the health and medical care of the Army, the Surgeon General had been cut off from direct access to the Chief of Staff and the Secretary of War. Professional personnel, for all practical purposes, was reduced to the status of rations and ammunition. As the Chief Surgeon of the American Expeditionary Forces protested when the change was made: "The present organization places a line officer of the General Staff in position to pass upon or present for higher consideration all matters of fundamental policy affecting the Medical Department. He can nullify the most carefully worked out program having for its object Medical Department efficiency." The Surgeon General, in short, could continue to raise his voice on medical matters, but he no longer had any certainty that it would be heard. He continued in this unhappy position in the interim between the wars and through most of World War II. By April, 1945, however, the anomaly of his status had given rise to so much confusion that it became necessary to clarify his duties and responsibilities by a War Department Circular, concurred in by the Secretary of War, who at that time assumed direct responsibility for the sick and wounded of the Army.

The anomalous position of the Surgeon General was responsible for many of the medical troubles encountered in World War II. Prestige cannot be established by regulations, rather, it is the product of successful achievement. Nevertheless, the position in which the Medical Department was placed in the organizational structure of the Army cannot be regarded as conducive to the enhancement of its prestige. The Surgeon General's advice might not be asked, even on matters that directly concerned the health and well-being of the troops. If it were requested or offered, there was no assurance that it would be accepted, translated into proper action or translated into any action at all. The situation demands correction. The Surgeon General must, of course, be subject in tactical matters to purely military command, but he must also again become master in his own medical house. His position must be so clarified that he can carry out his responsibilities and functions under the direction of a medically enlightened command, which is fully aware of the part played by the Medical Department in the actual business of warfare and which realizes, as Sir Alexander Hood has well put it, that "the medical services are the authorities on man and all that concerns him."

An important by-product of the anomalous position of the Medical Department in World War II was its lack of direct control over its own personnel. When that handicap was added to the structural organization without which, in spite of its cumber-

PROTEIN NUTRITION*

The Therapeutic Use of a Digest of Liver Protein, Especially in Patients with Cirrhosis of the Liver

JESSICA H. LEWIS, M.D.,† F. H. L. TAYLOR, Ph.D.,‡ AND CHARLES S. DAVIDSON, M.D., C.M.S.

With the Assistance of Margaret A. Adams, Jean V. Harrison, and Mary A. Maloney

BOSTON

IN THE treatment of many diseases it is often desirable to administer a part or, occasionally, all of the patient's food in a liquid form. Such a liquid formula should satisfy the nutritional needs of the patient in a concentrated, easily assimilable form. Particular interest has recently been evidenced in food supplements designed for patients needing additional protein. A high-protein intake has been shown to be especially desirable in certain conditions, such as cirrhosis of the liver,¹ nephrosis,² peptic ulcer,³ healing of surgical wounds⁴ and burns⁵ and states of malnutrition due to restricted intake.

The supplement¶ described in this paper is derived from liver protein by partial hydrolysis. Investigations on dogs with low plasma protein concentration due to depletion have shown that the protein of beef liver is active in building plasma albumin.⁶⁻⁸ This activity is not so effective as that of beef serum and egg white but about the same as that of beef muscle and casein. Thus, it was assumed before study that this protein would be adequate to maintain nitrogen equilibrium or a positive nitrogen balance in human beings, and the following investigation supports this assumption.

In addition to adequate protein, an ideal liquid supplement should contain sufficient energy value to prevent utilization of the protein for fuel. The liver protein hydrolysate contains only a small amount of carbohydrate and fat so that if the patient's diet does not furnish sufficient calories, sugar or starch or some other source of energy may be added to the liver protein digest. The liver protein digest contains ample amounts of most of the well known fractions of the vitamin B complex and is also a good source of the less familiar members of

this group but contains no appreciable amounts of the other vitamins.

A supplement should be as palatable as possible and free from disagreeable side effects. The liver

protein digest, flavored with chocolate, is palatable enough to be taken by most patients and, except for a laxative action in some cases, is without disagreeable side effects.

MATERIAL AND METHODS

Preparation and Composition of Liver Protein Digest

Liver protein digest is a dry, slightly hygroscopic, granular powder prepared by vacuum drying of a partial enzymatic (papain) hydrolysate of the liver pulp — the portion of the beef liver remaining after hot aqueous extraction of the anti-pernicious-anemia factor. The final powdered digest contains by weight

It has been conservatively estimated that the various governmental agencies supplying medical care will soon need half a million hospital beds. That is a third of the present hospital-bed capacity of the whole country. As the need for bed space multiplies, so will the need for professional personnel, particularly for specialized personnel, who cannot be supplied by the present system. Sane thinking therefore indicates the merger of the present separately maintained federal establishments, at least on the hospital level in the Zone of the Interior, which would reduce the needed professional personnel by 50 to 75 per cent, greatly increase efficiency of operation and greatly reduce costs. The conservation of specialized personnel, along with their efficient use, is one of the lessons that should have been learned for all time from the surgical experiences in World War II.

At present, from the standpoint of medical practice as well as in a number of other respects, we are acting from day to day. We have no plans and, worse, we have no principles to guide our course of action. Such a situation must not be permitted to continue. The surgical problems of World War II far exceeded in magnitude those of World War I. The problems of a possible third world war, about which we shall be criminally negligent if we are not entirely realistic, are likely to exceed to a staggering degree those of World War II. The end of World War II may indeed have marked the end of an era in military surgery, which for centuries had followed a pattern that, although progressively more demanding, was still essentially similar. Much of the knowledge we now possess, however, may become irrelevant and useless in this new era. There will necessarily be a new concept of war wounds. Radiation, blast and burn injuries of atomic origin will pose problems of management different from those hitherto associated with surgical care, and there must be a new concept of traumatic surgery in terms of regional injury.

Furthermore, the introduction of atomic weapons is likely to wipe out the old concept of echelons of combat and areas of security, and to bring civilians and military forces together into a single zone of combat. Atomic warfare is likely to cause an instantaneous flood of casualties, such as no battle

in the history of the world ever before produced. It will require the full use of all hospital facilities, on an over-all basis, with no wastage of beds, as well as the strategic placement of all equipment for general use as needed. Above all, it will require the mobilization of the entire medical personnel of the Nation on a disaster basis. There can be no distinction between military and civilian medical responsibility, for there will be no distinction between military and civilian injuries. It will require a mobility and speed of assignment of medical and surgical personnel such as has never before been necessary. There can be no more wastage of physicians. The problem, indeed, may be to keep the medical personnel of the country protected and alive and sufficiently uninjured to carry out their functions.

I should not like to end on this note. I do not believe that so dark a future will come soon, or that it is inevitable. But we should be lacking in realism and deserving of our fate if we did not face the possibilities frankly and take steps to forestall, prevent and prepare for disaster. Changes will be necessary: changes in the concept of medical education, changes in the methods of graduate education, changes in the plan of medical practice and changes in the relation and attitude of the civilian medical profession toward the federal medical services, including the Army and the Navy. To bring them about will take authority on a high level, which is now lacking on any level and which, when it is set up, must be exercised with wisdom and judgment and great discretion. Without medical statesmanship of a high order, these objectives cannot be attained.

Obviously, the experiences of World War II cannot be transferred directly to a possible atomic war. They must not, however, be discarded lightly. For the present, at least, they are all we have to go on. They supply some solid point of departure, in spite of the changes that must be made. The future of atomic warfare is uncertain, but the lessons of the last war will help, and certainly if we learn them, we shall be in a position of vantage that we have never before occupied at the beginning of any previous war.

In the 3 other normal subjects, nitrogen-balance studies were carried out after an initial period during which the patient received the 25-gm protein basic diet. The intake was 1900, 2500 and 4000 calories a day, depending on individual needs, and additional protein in amounts of 26, 50 and 46 gm daily respectively was supplied isocalorically by the liver protein digest.

A positive nitrogen balance was achieved in each case, and the level of plasma proteins remained normal throughout.

Plasma Protein Regeneration

In the normal group studied, no significant changes were observed in the plasma proteins,

edema had disappeared there was a gradual gain in body weight from 98 to 105 pounds. During the study the food and supplement furnished from 2000 to 3000 calories a day. A markedly positive nitrogen balance of about 20 gm daily was maintained during the entire period.

Liver Disease

Portal cirrhosis Nineteen patients in whom the diagnosis of portal (Laennec) cirrhosis had been made were studied. The past history in all revealed an excessive alcoholic intake and a food intake relatively low in protein and foods containing the vitamin B complex. The disease in these patients was roughly classified as mild, moderate and severe, on the basis of the duration of disease, physical examination and derangement of liver-function tests.

FIGURE 1 Nitrogen Balance Studies on Two Normal Subjects

which remained within the normal range throughout the study. This was also true of the patient with peptic ulcer and 3 patients with uncomplicated malnutrition. The results in liver disease are discussed below in connection with the other findings. The regeneration of plasma proteins was particularly striking in a patient with nephrosis, and this case is presented in detail.

L.P., a 38-year-old man with chronic glomerulonephritis and the nephrotic syndrome was given a diet containing 100 gm of protein and a supplement of liver protein digest containing an additional 100 gm of protein. On admission he had massive generalized edema, proteinuria and hypoalbuminemia. The proteinuria remained unchanged during the 50 days of study but, as shown in Figure 2, the edema disappeared, the body weight fell and the plasma albumin concentration rose from 1.5 to 3.5 gm per 100 cc. After the

(Table 2) In this connection the most valuable physical sign was the presence of ascites. Edema was present in only a few patients who did not have ascites. The liver size was not used as a criterion of the severity of the liver involvement in classification of the patients. Of the liver-function tests performed in this group, the cephalin-flocculation and thymol-turbidity tests had the greatest prognostic value. The bromsulfalein retention and the prothrombin time varied greatly and seemed to have little value in determining the severity of liver dysfunction or prognosis. The icteric index and serum bilirubin concentration were of importance only so far as they changed with the course of the disease and did not indicate the extent of permanent

54.5 per cent hydrolysate of the liver pulp, 37.8 per cent spray-dried malt and 7.5 per cent bitter chocolate

This preparation is naturally high in components of the vitamin B complex, with the exception of thiamine, which has been added. In Table 1, which shows the vitamin content as determined by the manufacturer, it can be seen that 100 gm of liver protein digest furnishes more than the National Research Council optimum allowances of thiamine, riboflavin and nicotinamide.⁹ Optimum values for the other components of the vitamin B complex have not been established, but moderate amounts of biotin, calcium pantothenate, folic acid and pyridoxine are present in this material. In addition, lipotropic factors, such as choline, inositol and methionine, are included.

Table 1 also shows the amino acid content of the liver protein digest. All the amino acids that have been shown to be essential in man¹⁰ are present.

The liver protein digest is easily suspended in hot water, although a precipitate settles on standing, this may be quickly resuspended by shaking. Usually, 180 gm of the digest dissolved in water to make 1 liter and containing approximately 100 gm of protein was given daily.

Nitrogen-Balance Studies in Normal Subjects

Food intake and nitrogen balance were studied in 5 normal persons in good nutritional status. Each received a basic diet containing 25 gm of protein and between 2000 and 4000 calories. Throughout the entire period of study the individual caloric intake was kept constant, and the protein studied was substituted isocalorically for carbohydrate. In 4 cases the activity of the liver protein digest was also compared with another protein of known biologic value. Daily determinations of the urine nitrogen were made by the micro-Kjeldahl method, and three-day or five-day determinations of the pooled stool by the macro-Kjeldahl method. Total plasma proteins and albumin globulin fractionations were determined by the Howe method.¹¹

Plasma Protein Regeneration

Plasma protein levels were followed in the 5 normal subjects, in 11 patients with portal cirrhosis of the liver, in 1 patient with nephrosis, in 1 patient with peptic ulcer and in 4 patients with uncomplicated malnutrition. The regeneration of the plasma proteins is discussed below.

Clinical Studies

Sixty-five patients received the liver protein digest daily over periods of one to seventy days. In 11 cases it was necessary to discontinue the study—in 3 because the disease had progressed to coma, in 3 because the patients refused to take the material, in 3 because of vomiting in 1 and severe diarrhea in 2 and in the other 2 because the patients were dis-

charged or transferred. Thus, 54 patients were studied, and the results of treatment are discussed below under the respective diseases.

Ten of the patients studied were placed on weighed diets and the caloric and protein intakes calculated. Most of the remaining patients received hospital diets, although a few were placed on special low-salt or Sippy regimes as required by the disease. Body weight was followed so far as possible in all patients. In patients with liver disease the serum bilirubin,¹² the cephalin-flocculation¹³ and thymol turbidity tests,¹⁴ the prothrombin time,¹⁵ the brom-sulfalein retention and the plasma protein concentration were followed.

RESULTS

Tolerance

Although the initial flavor of the liver protein digest is not distasteful, the preparation leaves a bitter liver taste in the mouth that to some is disagreeable. It was soon found that the psychologic introduction of this material as a medicine containing "liver and vitamins" obtained the co-operation and interest of the patients. A few patients, however, found the flavor so distasteful that the material could not be tolerated.

The laxative effect of the liver protein digest also limited its usefulness in some patients. This effect was particularly noticeable in patients who had gastrointestinal disorders associated with diarrhea, although even in some of these the diarrhea stopped after a few days of treatment with the liver protein digest. Most patients, however, noticed either no effect on their bowel habits or a slight increase in the number of bowel movements daily. This slight laxative effect could be ameliorated by urging frequent small feedings. Only one patient had diarrhea to such an extent that the digest had to be discontinued. The substance in the digest causing the laxative effect is not known but has been observed in the use of most oral liver preparations. It was certainly a major drawback to the usefulness of this protein digest in a few patients.

Nitrogen-Balance Studies in Normal Subjects

The results in 2 of the 5 normal subjects are demonstrated in Figure 1. These subjects were placed on a basic 25-gm protein diet, and after equilibrium or minimum negative nitrogen balance had been achieved, a lactalbumin preparation was given to raise the protein intake to 75 gm. After seven days these subjects were returned to the basic 25-gm protein diet for a short period, and a second trial period was then instituted by the addition of 50 gm of liver protein digest. The intake was maintained throughout at about 2900 calories. The amount of nitrogen retained during the administration of liver protein digest was even slightly greater than that during the administration of lactalbumin. Plasma protein concentrations remained at normal levels throughout.

revealed a long duration of the disease before the present admission to this hospital. Ascites improved in only 1 case, and in the other 4 repeated paracenteses were necessary. The plasma protein concentration was followed in 3 cases and showed little

by 5 patients with thermal burns. The data concerning these patients are presented in Table 7. All had severe burns. One patient (Case 36), with a third-degree burn of 46 per cent of the body surface, died on the thirteenth hospital day, nine days after the

change after treatment. The serum bilirubin concentration changed little during the period of treatment with liver protein digest.
Infectious hepatitis. Five patients with infectious hepatitis were given the liver protein digest in the same daily amounts as those given in cirrhosis of

initial administration of liver protein digest. In the others, who consumed variable amounts a day for periods ranging from thirty-two to seventy days, the nutritional status was either improved or maintained. In 2 patients (Cases 34 and 35) the liver protein digest was the chief source of protein during

the liver. Rapid improvement after the initial phase of the disease was observed in all patients, but from this small series it is impossible to conclude that the liver protein digest influenced the course of the disease. It was well tolerated in all cases after the initial acute gastrointestinal symptoms associated with the disease had improved.
Burns.
The liver protein digest was taken as a food supplement in amounts from 95 to 540 gm. a day

the period of administration. In the others various supplements, both oral and intravenous, were used.
A patient (Case 35) in whom the liver protein digest was the chief source of protein for a month, improved more rapidly during this period than during that in which he had received other protein supplements in approximately equivalent amounts. One patient (Case 34) developed a rash that was at first papular, and then became pustular and disappeared soon after the liver protein digest had been discontinued. This was the only suspicious sign of

damage or the prognosis. The total protein and albumin-globulin fractionation were not determined in all cases but showed definite trends in each group. In the mild cases the plasma albumin concentration was above 3.35 gm, and the globulin fraction concentration was below 2.8 gm per 100 cc. In the moderate cases the albumin concentration was

below the costal margin in the midclavicular line in only 2 cases. It seems likely that in this group the enlarged livers were due to fatty infiltration and the disappearance of this fat accounted for the rapid decrease in size. The plasma protein concentration was followed in 4 patients. Two showed an increase of plasma albumin concentration of about 1 gm. per

FIGURE 2 Essential Data in a Patient with Chronic Glomerulonephritis and the Nephrotic Syndrome

between 2.6 and 3.7 gm, and the globulin between 3.2 and 3.6 gm per 100 cc. In the cases classified as severe the plasma albumin was below 2.5 gm, and the globulin between 3.3 and 4.3 gm per 100 cc.

All patients received a daily supplement of liver protein digest containing 100 gm of protein in addition to a hospital diet supposedly high in protein and calories. No attempt was made to keep the fat low in these diets. In 6 cases the total caloric and protein intake was averaged for five-day periods from weighed diets (Table 3). The basic diet was planned to contain 300 gm of carbohydrate, 100 gm of protein and 50 gm of fat. The actual daily intake ranged from 1800 to 2800 calories and from 120 to 200 gm of protein.

Nine patients were classified as having mild cirrhosis. After receiving liver protein digest from twelve to thirty days, the improvement in this group was marked. Table 4 shows the most striking changes. The livers, which had been enlarged in all these patients before treatment, decreased in size after treatment and were palpable more than 1 cm

below the costal margin in the midclavicular line in only 2 cases. It seems likely that in this group the enlarged livers were due to fatty infiltration and the disappearance of this fat accounted for the rapid decrease in size. The plasma protein concentration was followed in 4 patients. Two showed an increase of plasma albumin concentration of about 1 gm. per

100 cc, whereas in the other 2 the albumin concentration remained constant or slightly decreased. In only 1 patient (Case 4) was there an increase in plasma globulin. The serum bilirubin concentration was elevated in 6 cases, in all of which the total bilirubin decreased to normal, although the direct reacting bilirubin remained elevated in 4.

In the 5 cases classified as moderate, 4 patients showed marked and 1 moderate improvement (Table 5). Ascites and edema decreased or vanished, and the liver size diminished. The plasma proteins were determined in 4 patients of this group, the plasma albumin concentration remained constant in 1 and was increased in 3. The globulin concentration increased slightly in 3 patients. The serum bilirubin determination was followed in only 2 cases, in which it decreased to normal total bilirubin concentration, although 1 patient continued to have an elevated prompt, direct bilirubin concentration.

In the group of 5 patients with severe cirrhosis, 3 died and the others showed only minimal improvement (Table 6). The past histories in these patients

and showed only slight improvement. The remaining 10 patients received the liver protein digest for nine to twenty-three days with moderate to marked improvement. Weight gains ranged from 1 to 10 pounds, averaging 6 pounds for a two-week period of treatment. The 3 postoperative patients showed rapid wound healing and weight gain. The patient with hemophilia had an ulcer on the left leg and was

in this group. In another patient, a seventy-five-year-old woman with a poor dietary history, the initial total protein concentration was 4.8 gm, with an albumin concentration of 1.71 gm per 100 cc. For fifteen days she received 100 gm of protein from liver protein digest, in addition to a diet containing 50 gm of protein and about 1200 calories, and during that time the total protein rose to 6.18

markedly underweight. After ten days of treatment the ulcer was almost completely healed, and the patient had gained 6 pounds.

Nitrogen balances were followed in 4 patients, in 2 of whom the liver protein digest was given to total 50 per cent of a 200-gm protein diet (2300 to 2700 calories). These two patients retained an average of 11.7 and 7.6 gm of nitrogen daily over a ten-day

period, with an albumin concentration of 3.30 gm per 100 cc although she gained only 4 pounds.

DISCUSSION

Good food, properly selected and in adequate amounts and taken by mouth, is the most effective and satisfactory method of supplying essential nutrients. Purified diets may lack some essential

period. Another patient, who received 65 gm of protein from the liver protein digest and a basic diet containing 75 gm of animal and vegetable protein, retained an average of 8.6 gm of nitrogen daily. The last patient, an alcoholic addict, was put on a basic 25-gm protein diet for ten days, during which he was in nitrogen equilibrium. At that point, liver protein digest was added isocalorically to the diet, bringing the protein intake to 75 gm daily over the next ten-day period. This patient retained an average of 5.7 gm of nitrogen daily.

Plasma proteins were followed in 3 of the 4 cases in which nitrogen balances were determined. The plasma protein concentrations were not abnormal

as yet unknown. Thus, monkeys fed purified diets containing all the known dietary essentials fail to gain weight and develop a macrocytic anemia that is cured by liver.¹⁶ This missing component has recently proved to be the synthetic *Lactobacillus casei* factor.¹⁷ In view of this and similar investigations, it is unlikely that all the essential nutrients are known. It seems, therefore, a good practice to supply natural foods or their derivatives as sources of calories, protein and vitamins. Recently, it has become the custom for physicians to prescribe large amounts of one vitamin or a multivitamin capsule for their patients. The administration of large amounts of a single vitamin to the exclusion of others

sensitivity in any of the patients treated with the digest

Peptic Ulcer

Liver protein digest was administered to 3 patients with duodenal ulcer. In 1 of these it was used as a supplement to a soft diet and in the other 2 as the

the diarrhea was aggravated. Nevertheless, during that time, the patient gained 5 pounds in weight, and the symptoms and signs of peripheral neuritis, which had been relatively acute at onset, were markedly diminished. The other 2 patients, both with a longer history of peripheral neuritis, had gradual improvement such as one would expect with

sole source of oral protein for three to five days. These last 2 patients are of interest in that they were admitted with marked pyloric obstruction and almost complete gastric retention. The liver protein digest was administered through a gastric tube at hourly intervals, and gastric contents were aspirated to relieve distention. This was necessary every four hours for the first twenty-four hours, but by the third or fourth day the obstruction had been completely relieved and aspirations were no longer necessary. The patients were then placed on a soft diet, and liver protein digest was given as a supplement. The weight gains in these patients were remarkable, 1 patient gaining 18 pounds in ten days,

optimum vitamin therapy. Approximately 180 gm of the liver protein digest was administered daily for thirteen and forty-eight days respectively, when the patients were discharged from the hospital.

Malnourishment

Fourteen patients exhibiting various degrees of malnutrition due to restricted food intake were studied. In 6 the restricted diet was voluntary and was usually accompanied by chronic alcoholism. The remaining patients had a variety of conditions, including bronchiectasis, Parkinson's disease, healed duodenal ulcer, hemophilia, hypernephroma and postoperative malnourishment. These patients re-

TABLE 5 Changes Observed during Treatment with Liver Protein Digest in Patients with Moderate Cirrhosis

and the other 10 pounds in six days. More studies are being carried out on patients with peptic ulcer. No conclusions can be drawn from this series, but the results, particularly in obstructive lesions, are hopeful and are similar to those recently reported by Co Tui² with a casein hydrolysate.

Peripheral Neuritis

The liver protein digest was given to 3 patients with peripheral neuritis associated with chronic alcoholism. In 1, a thirty-one-year-old woman with moderate diarrhea on admission, the liver protein digest had to be discontinued after five days because

ceived the liver protein digest in amounts of approximately 100 gm of protein daily for four to twenty-three days. Whenever possible, changes in body weight were observed, and in 4 patients nitrogen balance and plasma protein concentrations were followed.

No improvement was shown in 2 patients — one with a hypernephroma extending into the hepatic vein, who developed marked ascites and eventually died, and the other, a patient with Parkinsonism who presented a feeding problem and was transferred to a nursing home. Of the other patients, 2 were followed for four and five days respectively.

SUMMARY

A partial enzymatic digest of liver protein was administered as a food supplement to 65 patients. The digest contained 60 per cent protein, in addition to relatively large quantities of vitamin B complex.

The taste of the liver protein digest is somewhat disagreeable, and a laxative effect was observed in some patients.

The liver protein digest supported positive nitrogen balance or nitrogen equilibrium when given as the chief source of protein to 5 normal subjects and 4 malnourished patients.

Plasma protein regeneration was demonstrated in 1 patient with nephrosis and in 1 with uncomplicated malnutrition, as well as in several patients with cirrhosis of the liver.

The results of the treatment of 19 patients with portal cirrhosis of the liver was at least as satisfactory as those attained with other means of supplying the many nutrients that have recently been advocated for the treatment of this disease. The recovery of 5 patients with infectious hepatitis progressed satisfactorily.

The liver protein digest proved to be an adequate protein supplement for 4 of 5 patients with severe thermal burns.

The digest was given to 3 patients with peptic ulcers, 2 of whom had marked pyloric obstruction. The results in these 3 patients were excellent.

Recovery in 3 patients with alcoholic peripheral neuritis who received the liver protein digest was approximately the same as was expected from the duration and severity of the condition.

Fourteen patients with malnourishment of various causes received the liver protein digest. Marked improvement was observed in 10.

may be dangerous,¹⁸ and few multivitamin capsules can be considered to supply in optimum amounts all the nutrients falling into this class. It seems evident, therefore, that a natural product containing the known essential nutrients is the best means of supplying a diet supplement. The liver protein digest admirably meets these requirements so far as protein and the vitamin B complex are concerned. It should be emphasized, however, that the digest does not provide other vitamins or sufficient calories in itself to prevent the burning of protein for energy.

Mixtures of nutrients in various combinations and amounts have been used as diet supplements for years and have recently been re-emphasized in protein feeding.^{19, 20} In many cases they form the greater part of the food intake and thus must be planned with care to meet all the possible requirements. This is difficult for the physician without a particular interest in nutrition, especially in providing the vitamin B complex, and the liver protein digest, given with sufficient calories, vitamin C and, if necessary, the fat-soluble vitamins, therefore forms an important addition to the dietary armamentarium.

In addition to supplying nutrients, a food supplement should be palatable and without unpleasant side-effects. The bitter aftertaste of the liver protein digest is unpleasant to many patients, and in fact some took it only because they were convinced of its value. A few could or would not take the mixture at all. The laxative effect of the digest was also severe enough in some patients to require discontinuance of the mixture. Many others had an increase in the number of bowel movements a day that was not distressing, however.

That the liver protein digest will maintain nitrogen equilibrium in normal subjects when it is used as the chief source of protein is clearly demonstrated in the 5 normal persons described above. Furthermore, in 4 patients who had lost weight it was possible to maintain a strongly positive nitrogen balance. Plasma protein regeneration with a strongly positive nitrogen balance was evident in a patient with nephrosis, in whom the liver protein digest formed about half the protein intake, and in a patient with severe malnutrition.

Recent studies have emphasized the value of food intake in the treatment of portal cirrhosis of the liver. Special emphasis has been placed on protein and the vitamin B complex,¹ methionine and choline.^{21, 22} The presence of these substances makes the liver protein digest theoretically exceptionally good in the treatment of this condition. The results in the 19 patients with cirrhosis support this view. In our experience, the improvement was at least as good if not somewhat better than that with any other means of administering the food elements necessary. These results, in addition to the relative ease of administration of such a diversity of substances, make the liver protein digest extremely

useful in the specific therapy of cirrhosis of the liver.

It has been repeatedly pointed out that the nutritional requirements of patients with thermal burns are high.^{5, 23} This is especially true of protein, large amounts of which are lost from the burn surface²⁴ and in the urine as nonprotein nitrogen.²⁵ These patients are usually extremely ill and have marked anorexia so that attaining the nutritional requirements is often difficult and requires frequent changing of the dietary supplements to add variety to the food intake. In this way the liver protein digest formed a useful protein supplement in the patients studied and proved to be at least as satisfactory as the other supplements used.

Peripheral neuritis in alcoholism is generally regarded as a deficiency disease,²⁶ thiamine being specifically implicated.²⁷ Most patients with this condition have evidence of multiple dietary deficiencies so that rational therapy should be directed toward a more complete replacement therapy than with thiamine alone. The results presented above do not indicate any more beneficial effects than those afforded by other means of attaining adequate intake of nutrients, in fact, in a patient with peripheral neuritis complicated by diarrhea, the digest had to be discontinued because of increase in the latter symptom. Nevertheless, the improvement in all 3 patients with peripheral neuritis was about what one would expect from optimum dietary therapy. More than 10 mg of thiamine was supplied daily to these patients in food and liver protein digest.

The etiology of peptic ulcer remains unknown, although there is no doubt that psychologic factors play an important role. Many patients suffering from peptic ulcer improve markedly under almost any regime that offers relief from psychologic problems, as well as under local and general medical treatment. Local treatment of the ulcer is best achieved by reduction of gastric acidity through the use of buffering substances. General medical treatment includes hydration, regulation of acid-base balance and improvement of general nutrition. Obstruction of the pylorus in peptic ulcer may be due to either edema or scar formation. It is often difficult to differentiate these conditions without a therapeutic trial. In the 2 cases of ulcer discussed above complete six-hour gastric retention was shown by x-ray study before treatment. It was believed by many observers that the obstructions were due to scar formation, and we were surprised at the rapidity with which these obstructions were relieved, indicating that they had been due to edema and inflammation. The liver protein digest offers an excellent buffering agent as well as a good food and if given at frequent intervals seems to offer a satisfactory method of treatment. More studies will be necessary to determine the efficacy of this therapy in ulcer patients.

quite certain even without roentgenologic study. Hyperextension of the knee is often so marked that the lower leg is brought into contact with the thigh. The skin in front of the knee is slack and wrinkled, the patella being palpable but smaller than that of the opposite leg. Occasionally, the patella seems to be absent. The condyles of the femur and the tibial displacement are palpable, and the loss of flexion is obvious. When these findings are present, the diagnosis is established. In roentgenologic studies confirmatory evidence is offered, but it must be remembered that the joints are largely cartilaginous so that a clear picture of the relation of joint surfaces to each other cannot with certainty be obtained. In these cases, however, the angle and displacement between axes of the tibia and femur will be noted.

Early, conservative, manipulation of the knee is the most efficient method of therapy. In the majority of cases in which conservative treatment was instituted soon after birth, excellent anatomic and functional results were obtained. The longer the treatment is delayed, the more difficult the therapeutic procedures required and the less favorable the results. At a later period, surgical intervention is often necessary, and regardless of the treatment the reports show poor end results when compared with those in patients treated early.

The type of conservative method used differs depending on the surgeon. Essentially, the procedure consists of early reduction and maintenance of the reduced position followed by a gradual increase in flexion. When the patient begins to walk, a lateral knee brace or knee cage may be necessary.^{54, 55}

CASE REPORT*

A female infant, the head presenting, was delivered normally after 8 hours of labor. The birth weight was 7 pounds, 14 ounces. There was no family history of congenital lesions. Seven days after birth, except for the findings limited to the right leg, physical examination revealed a normal infant. The right leg was hyperextended. The skin over the knee was loose and markedly wrinkled. The tibia was anterior to the femoral condyles, the distal end of the femur projecting posteriorly to the proximal portion of the tibia. The patella, located above the knee joint, was smaller than that of the left leg. There was laxity of the collateral ligaments.

On reflex action, the right lower leg was hyperextended on the femur to about 90 to 110°. From this point, the lower leg could be painlessly hyperextended to the thigh. Flexion could not be obtained unless traction was first applied to reduce the dislocation, when the leg could be straightened. Clicking of the knee joint was noted as the tibia passed over the distal end of the femur. The left leg was normal.

Treatment, which was started immediately, consisted of traction on the femur to reduce the dislocation. A malleable aluminum posterior splint was applied to maintain the position of the leg in 180° extension. On the 2nd day, the splint was removed and flexion was increased, heat and massage being applied to the hamstrings and the quadriceps muscle. This procedure was repeated daily, allowing an increase in passive motion of flexion and extension to 180°. The attained position of flexion was maintained and increased by the use of the aluminum splint. Within 2 weeks, flexion was complete, but hyperextension was not allowed. Within 4 weeks, the splint was removed, and the knee did not dislocate.

Although it was not deemed necessary to keep the splint applied, it was used 4 weeks longer, after which it was removed. During the manipulations no anesthesia was necessary.

On weight bearing, the leg appeared normal. After 3 years, examination of the right leg revealed no abnormal findings, and the child was able to run, play and jump as well as any other child her age.

SUMMARY

An etiologic classification of dislocations of the knee is presented. The diagnostic features are discussed. The incidence of the condition in relation to sex, types and familial tendencies is described. The comparative results of various treatments are mentioned. A detailed case presentation is given.

In the treatment of congenital dislocations of the knee, the end results obtained are dependent on the etiologic factor involved and the time at which treatment is instituted. In patients with traumatic developmental lesions, excluding those with secondary malposition, early conservative treatment, even without anesthesia, results in normal anatomic and functional knee joints. In the presence of multiple lesions, the final outcome depends on the seriousness of the other congenital anomalies present. The necessary surgical procedures often used in the treatment of this lesion cannot compare with the results of early conservative therapy.

CONGENITAL DISLOCATION OF THE KNEE*

Report of a Case

R WILLIAM PROVENZANO, M D †

BOSTON

ALTHOUGH congenital dislocation is extremely rare, it is the most frequent congenital deformity of the knee. In recent years the occurrence and the treatment of this lesion have received considerable attention,¹⁻³⁶ but to date an etiologic grouping has not been presented. It is the purpose of this paper to formulate an etiologic classification of congenital dislocations of the knee, to review the various cases reported to determine the incidence in relation to hereditary tendencies, sex and types of dislocations, to discuss the numerous treatments prescribed and to present the case of a patient treated by simple conservative manipulation and early physiotherapy and followed for a period of three years.

Many theories have been advanced regarding the cause of congenital dislocations of the knee^{16, 17, 26, 33, 36-50}. Drehmann,³⁸ Mayer³⁷ and others^{6, 39, 51, 52} believe that malpositions in utero are the primary causative factors, genu recurvatum and true dislocations being different only in severity. Hussein² and Kopits¹⁰ consider mesenchymal defects the cause of multiple and universal abnormalities. McFarland¹ and others^{12, 15, 28} believe the lesion to be due either to a primary defect or to malposition in utero. Magnus⁴⁰ and others^{41-43, 45, 47-50} regard an intrauterine fetal illness as the cause.

In a determination of the etiologic factors involved, intrauterine or intrinsic causes and extrauterine or extrinsic causes must be considered. The former refer to dislocations arising from maternal or fetal intrauterine disturbances, and the latter to factors other than those related to maternal or fetal conditions, such as the necessary manipulations performed by the obstetrician during the process of delivery. The intrauterine or intrinsic causes can be divided into primary mesenchymal defects and traumatic developmental defects, the latter may be subdivided into developmental malposition in utero occurring during the developmental processes, secondary malposition in utero superimposed on a previously existing mesenchymal defect and malposition assumed during the actual process of delivery.

The severity of the condition seen at birth and the prognosis are dependent on the causative factor or factors involved. In the patients with primary defects, the lesions are usually multiple and there-

fore more difficult to treat, and the prognosis is necessarily based on the outlook for the other existing anomalies. In the traumatic group the lesions are usually single or bilateral, except for dislocations superimposed on a pre-existing mesenchymal defect, in which group multiple lesions are found. That this type can occur is shown by McFarland,¹ who reports a case in which x-ray findings before delivery revealed a fetus in utero with one leg flexed and the other hyperextended and in which other deformities were found at birth. The dislocations seen in the traumatic group when not complicated by other congenital deformities yield excellent results with simple conservative manipulation, provided treatment is instituted early.

A review of the literature reveals that neither familial nor hereditary factors truly influence the incidence of congenital dislocations of the knee. In addition, an attempt was made to determine whether or not acute maternal illnesses caused predisposition to the development of these congenital defects. It was noted that there was no relation between acute infectious diseases occurring in the mother during pregnancy and the development of this anomaly in the newborn. Of 212 patients whose cases were reviewed, a family history of a similar defect or some other congenital deformity was reported in only 7. In 174 cases the occurrence of acute maternal illnesses was denied. No mention of virus infections in the mother was made.

Against the belief of Muskat⁴¹ and others^{12, 28, 45} who state that these dislocations occur twice as often in girls, it was found that of the 212 cases of congenital knee dislocations, 101 appeared in males and 111 in females. It was also shown that the types of lesions were distributed about equally between the sexes. The types of dislocation included 155 cases of single dislocations and 57 of multiple deformities. Of the 155 patients in whom the knee was the only deformity noted, 95 showed unilateral and 60 bilateral dislocations. Of the 57 patients with multiple deformities, 31 presented unilateral and 26 bilateral dislocations of the knee. Kopits¹⁰ observed that among 2393 cases of congenital deformity there were only 11 of dislocation of the knee as compared with 923 of congenital dislocation of the hip.

In congenital dislocations of the knees, the findings described by the various investigators^{3, 6, 7, 9, 11, 21, 33} are essentially the same, and although the lesions are sometimes difficult to classify, the diagnosis is

plastics methyl methacrylate (Lucite and Plexiglas), "nylon," a generic term applied to a group of polyamides, vinyl resins (Vinylite), polyethylene (Polythene), and cellulose nitrate (celluloid) and regenerated cellulose (cellophane). It should be stated that on rare occasions plastic materials have been selected for use in the body because of their ability to set up a moderately intense reaction and to stimulate the formation of scar tissue. This subject is discussed below at greater length. Each of the plastics mentioned above is considered in a separate section of this report.

A brief account should first be given of the chemical and physical properties of plastics in general. A plastic is a solid material that contains as an essential ingredient an organic substance of large molecular weight and that, at some stage in its manufacture or in its conversion into end products, is capable of being shaped by flow.¹ The Plastics Materials Manufacturers Association has defined plastics as synthetic organic materials that, through application of pressure or heat, or both, may be fashioned into almost any desirable shape, varying from solids capable of fabrication by turning on a lathe to liquids that can be sprayed. Industrial plastics have been divided by Kline² into four categories: synthetic resins, natural resins, cellulose derivatives, and protein substances. It is not proposed to discuss the natural resins or the protein substances, since they are composed of complex chemical structures that are often not purified and have not been found suitable for use in tissues. Cellulose derivatives are primarily of historical interest, except for the isolated use of materials to stimulate scar tissue.

Interest is centered chiefly around the synthetic resins, many of which have simple chemical structures. The chemist has been able to synthesize materials that have the hardness of stone, the transparency of glass, the flexibility of rubber or the insulating ability of mica. In general, organic plastics are resistant to atmospheric and chemical corrosion and possess high structural strength, light weight, low heat conductivity and good electric-insulation value. The synthetic resins found most satisfactory for use in surgery are as a whole composed of long-chained polymers of simple monomeric structure. These have been converted into polymers by the influence of catalysts or by the effect of light, heat, oxygen or extreme pressure.

Synthetic resins are either thermosetting or thermoplastic. Thermosetting plastics are made extremely hard by heating, and their value in industry in general depends on this quality; this group has not been used in surgical procedures. Thermoplastic products are fusible, soften when heated and become hard again when cold.³ The extremes of temperature variation in the animal or human body are not sufficient to alter the physical properties of any thermoplastic materials signifi-

cantly. It is therefore with the thermoplastic synthetic resins that this paper is chiefly concerned, and the subsequent discussion centers around this group. Some of the plastics found useful in surgery are hard, and are employed because of that property, such a material is methyl methacrylate. Others, like polyethylene, are used because they are pliable and soft and are suitable for surgical application because they attain this softness through their own structure and not by the addition of plasticizers.

Most thermoplastic linear polymers of high molecular weight are hard, brittle solids at room temperature. On heating they soften and gradually become more flexible and plastic. The flexibility at room temperatures can be increased by the addition of materials of relatively low molecular weight, called "plasticizers." A great variety of plastic materials have been made available to industry by the use of such plasticizers.⁴ Plasticization is essentially a separation of chain molecules by the plasticizer molecules converting hard plastics with long-chained molecules into pliable plastics with shorter molecules. Camphor, tricresyl-phosphate, glycerol and many other chemicals have been utilized as plasticizers. Plasticizers usually remain within the plastic material, and most of them have been found to be irritating to human and animal tissues.⁵ It seems safest, therefore, to exclude from surgical usage all plastics that contain plasticizers, unless in the future varieties can be found that are not tissue irritants. This, of course, greatly narrows the field of potential plastic substances available to the surgeon.

METHYL METHACRYLATE

This long-chained polymer has been used more extensively and with greater success in both experimental and clinical surgery than any other synthetic resin. It is produced commercially under the trade names of "Lucite" and "Plexiglas" but is generally known as acrylic, particularly in the field of dentistry. In England it is frequently called "Perspex."

Methyl methacrylate is obtained by the polymerization of derivatives of acrylic acid. Under the influence of heat, light and such oxygen-yielding substances as hydrogen peroxide, the esters of acrylic acid and methacrylic acid polymerize through various stages to form methyl methacrylate.⁶ This substance is considered to exist in chains of various lengths, formed by the linking together of the original monomeric molecules.

Methyl methacrylate can be cast in the form of sheets, rods or tubes, or it can be cast in a mold to any form desired. It has many advantageous physical properties. It is hard and tough, has high tensile strength, and is light, with a specific gravity of 1.18 to 1.20. It is chemically inert and stable, has negligible water absorption, is transparent, and has a high velocity resistance.^{7, 8} It is nonporous, and its surface is impervious to the ingrowth of bacteria, hence, it is easily sterilized. It has been found to

MEDICAL PROGRESS

SYNTHETIC PLASTIC MATERIALS IN SURGERY*

FRANC D INGRAHAM, M D,† EBEN ALEXANDER, JR., M D,‡ AND DONALD D MATSON, M D‡

BOSTON

THE last thirty years have witnessed a tremendous growth in the plastics industry, and a great variety of new plastic materials have been developed. In the field of medicine they have been used chiefly in the production of surgical and medical diagnostic and therapeutic instruments. A limited application of plastic materials buried within the human body has been found, however, and it is with this use of plastics that this progress report is concerned. No attempt is made to review related medical fields, such as dentistry.

The selection of plastic materials for use in the body has been in large part fortuitous. Without previous laboratory trial, various plastics possessing certain desirable physical properties were employed sporadically in operative procedures. Some of these were well tolerated in the body, others were quite severe irritants to tissues. In more recent years, an increasing number of papers dealing with experi-

mental surgery using plastics appeared. One plastic material, methyl methacrylate, was found to be well tolerated in the mouth by dentists, and was subsequently utilized by surgeons.

✓ Certain general criteria should be met in the selection of any substance to be buried in human tissue. The material should be nonabsorbable and not modified by tissue fluids, chemically inert, free from excitation of early or late tissue reaction, non-epileptogenic when buried in brain tissue and non-carcinogenic. There are rare exceptions, but in general any solid plastic to be used in normal human tissue should satisfy these criteria.

Industry has developed literally thousands of varieties of plastic materials, and at first sight the wealth of information available is overwhelming. A careful selection of materials that fulfill specific surgical needs quickly limits the number of these substances that require investigation. Animal experimentation should be carried out to determine the reaction of individual materials in tissue before these substances are used in the surgery of human beings.

Sufficient experimentation has been done to warrant discussion of the following well known

*From the Neurosurgical Service, Children's Hospital, and the Department of Surgery, Harvard Medical School.

ack in small skull defects by the use of preformed acrylic plates of various sizes, which he put in place at the time of the primary operation. He used these only in patients without neurologic deficit and in those in whom the dura was intact. He reported 48 cases in which this technic was employed.

Blum²⁶ refers to another method of speeding up the process of polymerization of methyl methacrylate. This is done by the addition of a special catalyst, whose composition is not given, to the methyl methacrylate "dough." The material is exposed to ultraviolet rays, and the process of polymerization requires only fifteen minutes. Blum stated that the substance did not produce dural reaction or changes in the underlying brain tissue. The same method is mentioned in a later publication²⁷, in addition, reference is made to the fact that methyl methacrylate sheets can easily be molded at 130°C. If rapidly cooled, they will retain the shape into which they have been molded and can be boiled or autoclaved. These methods will contribute significantly to shortening the operating time in cranioplasty with methyl methacrylate.

Acrylic has been used in several other areas of the body to replace the metallic alloy, vitallium. It is considered by some to be ideal for arthroplasty, particularly in arthritis of the hip. Harmon²⁸⁻³¹ has described the use of acrylic in hip arthroplasties in several reports and is enthusiastic about the results. In his last report he had done hip operations with acrylic cups in 16 cases. The results were excellent in 62 per cent, good in 19 per cent and poor in 19 per cent. He believed that the poor results in 2 of 3 cases were due to error in selection of cases. The relief of pain in arthritis of the hip was reported as dramatic in many of the cases. Burman and Abrahamson¹⁵ employed acrylic in arthroplasty of the hip in 1 case and of the finger in 2, with good results.

Methyl methacrylate has also been used in plastic surgery for sculpturally molded implants in facial deformities, as described by Brown³² and by Penhale.¹¹ It has been implanted in the scrotum in patients who had had previous orchidectomies.³³ In addition to being light and well tolerated in the scrotum, the implants provided considerable cosmetic improvement and psychologic comfort. After a year in place, they showed no evidence of unusual tissue reaction to gross palpation.

Dennis¹⁶ implanted specially formed methyl methacrylate tubes into cavities of the long bones of patients with chronic osteomyelitis. He reported that the tubes stayed in place twelve to fifteen months and were well tolerated, and that satisfactory healing of the chronic infections took place as a result of this procedure.

In the field of experimental medicine, Sohler, Lothrop and Forbes³⁴ first made use of Lucite windows screwed into the skulls of animals with

the acrylic in contact with the brain. These were employed to observe the circulation of blood over the cortex for a period of many weeks without the occurrence of infection. An excellent elaboration of this technic has been described by Sheldon et al.³⁵ who were able to fashion a transparent Lucite calvarium covering the entire top of a monkey's head. This was held in place with screws. Several of the coverings were left in place for many months. This type of experiment offers an exceptional opportunity for observing the surface of the brain under essentially normal conditions of intracranial pressure and cerebral circulation. Owing to the lack of reaction to methyl methacrylate, the scalp edges around the base of the plate healed rapidly and showed no infection.

Merendino and Litow⁷ fashioned gastrostomy tubes that could be maintained in position in experimental animals for several months. They suggested the use of this material for gastrostomies in human beings but did not report any such cases.

A little known property of methyl methacrylate is that described by Hirschboeck,³⁶ who found that tubes and small containers made of methacrylate possessed an anticoagulant power that he believed to be due to the pronounced water-repelling property of the surface of the material. The coagulation time in Lucite tubes is approximately twice as long as that in glass. The application of this property to the use of acrylic in vascular surgery suggests itself. Brief reference to this possibility is made by Mustard,³⁷ although he refers to no specific type of plastic material.

Hufnagel³⁸ performed a series of anastomoses of the thoracic aorta in 18 dogs after resecting 1 to 3 cm of the aorta. He used tubes of methyl methacrylate 4 cm in length and 1.0 to 1.3 cm in diameter, with walls 1 mm thick, to bridge the gap. Particular care was taken to polish the inner wall of the tubes so that there were no rough areas or irregularities. These tubes were tied in place with two braided-silk sutures at each end of the tube. Six dogs died of hemorrhage seven to ten days after operation, owing to cutting through of the suture, but this was obviated in later experiments by the use of a coarser braided-silk suture that gave multiple point fixation. The striking result of these experiments was that thrombosis did not occur in a single animal either in the tube or in the aorta. Some of the animals lived as long as six months in excellent health.

DeBakey and Simeone,³⁹ in a discussion of the treatment of arterial injuries in battle wounds of 2471 soldiers in World War II, mention the occasional use of plastic tubes in vascular anastomosis. They found records that this method had been used in 14 cases, but the type of plastic employed was not mentioned. The results, which were not recorded in individual cases, were discouraging in general. The authors believed that blood was

be nonabsorbable in human tissues and unchanged when buried in them. It retains its form and does not begin to soften until heated above 150°F. In repeated reliable experimental and clinical studies, it has been shown to be well tolerated in both animal and human tissues.

Mackenzie, Sharpless and Millard⁹ performed animal experiments to compare the reaction of tissues to vitallium, ticonium and acrylic. Histologic studies were done at intervals, and photomicrographs are published in the paper. Acrylic was found to cause no inflammation whatever. A thin, fibrous, tissue membrane that became increasingly dense over a six months' period formed around the material. Vitallium and acrylic were tolerated about equally well in the short series of experiments, ticonium was less satisfactory.

Beck et al.¹⁰ buried disks of acrylic in the skulls of rabbits. They used 16 animals, in half of which they removed the dura under the disk, and sacrificed the animals at intervals up to seven months. The plastic was well tolerated, being surrounded by a thin, fibrous, tissue capsule, to which it was not adherent. In some animals in which the underlying dura had been removed there were mild adhesions between the thin fibrous capsule and the leptomeninges, but the brain was normal in all. The photomicrographs showed no evidence of foreign-body reaction to the acrylic, which was considered to be well tolerated.

Woolf and Walker¹¹ also presented photomicrographs of acrylic buried in tissues over a prolonged period in which the plates were encapsulated by a thin layer of connective tissue. Acrylic did not incite any foreign-body reaction even in the presence of wound infection. This has been borne out clinically by Elkins and Cameron,¹² who reported 70 cases of cranioplasty in combat wounds of the head. They found no complications attributable to acrylic, some of their plates had been in place two years. In one case in which infection occurred, the plate was not removed, and the wound subsequently healed satisfactorily. There are other scattered reports of the effect of acrylic on tissues. Penhale¹³ buried acrylic in the subcutaneous tissues of monkeys for seven days. Reproductions of the histologic sections showing the slight reaction that occurred were published. The reaction was much less than that caused by cartilage or ivory. Penhale reported several patients who had had implants in place for the correction of facial deformities for over three years without complications.

Burman¹⁴ and Burman and Abrahamson¹⁵ describe methyl methacrylate as reactionless, gross and microscopical studies of the subcutaneous tissue of rabbits after implantation of the material showed no reaction after eighty days. They performed three arthroplasties using this material with satisfactory results. Dennis¹⁶ observed that Lucite caused no significant reaction in the muscle of a dog after

thirty days. Davis⁸ states that the acrylic used in protecting helmets for airmen causes no unfavorable reaction if accidentally driven into tissues.

Spealman and his associates¹⁷ studied the toxicity of methacrylates by oral, intraperitoneal and subcutaneous administration and by inhalation. The monomeric form was mildly irritating, but in the final polymeric form the acrylic showed no irritation and no tendency to sensitize animals. Implantation in subcutaneous tissues of mice provoked no tumor growth.

The medical literature on this particular synthetic resin is more extensive than that on any other. The material has been adequately tested and found suitable for a variety of surgical uses, some of which have also been reviewed by commercial publications.¹⁸

Methyl methacrylate is admirably suited for the repair of defects of the skull. As suggested by Woolf and Walker,¹¹ nonmetallic alloplastic grafts for skull defects should fulfill certain criteria: they should be inert and not modified by tissue juices, they should not be epileptogenic or carcinogenic, they should be sufficiently rigid to maintain contour, they should offer little or no resistance to x-rays, and they should cause little or no immediate or late tissue reaction. Methyl methacrylate meets these standards adequately, and a number of reports of its use in cranioplasty attest its value.

The article of Elkins and Cameron¹² mentioned above presents the largest reported series in which acrylic was employed. Woolf and Walker¹¹ considered it one of the most satisfactory materials for cranioplasty. Gurdjian, Webster and Brown,¹⁹ Lambros,²⁰ Woodhall,²¹ Kahn²² and Kerr²³ describe methyl methacrylate as a satisfactory material for cranioplasty. Small and Graham²⁴ recently reported the use of methyl methacrylate for the closure of skull defects in 25 patients. They had only one failure, in a patient in whom there had been a previously infected subdural hematoma. Their paper, profusely illustrated, describes in great detail the technic of forming and inserting the plates.

The acrylic plates are made by the impression technic, which requires either a two-stage procedure or a delay of about one and a half to four hours during an operation while the plate is being formed. Its use is somewhat more complicated than that of tantalum, but because it is not opaque to x-rays and can be fashioned somewhat more satisfactorily to obliterate dead spaces in tissue, it is probably superior to that material for cranioplasty in most cases. Acrylic is considered easier to use than vitallium. Since it is widely employed in dental laboratories, the co-operation of a dentist in any large hospital facilitates its use.

One of the strongest objections to methyl methacrylate for cranioplasty is the time required to form the plates. Shoreston²⁵ has circumvented this draw-

proved Burman believed that nylon used in this way caused a certain amount of serous fluid to collect around it, a property that he regarded as desirable in this operation.

Weiss and Taylor⁵⁰ employed multiple fine strands of nylon to aid in bridging nerve gaps in experimental animals. By an ingenious technic worked out by them, the gap between the nerve ends is bridged by the nylon fibers and filled with solid blood clot. This is covered by collagen or some other sheath to prevent the ingrowth of scar tissue. Weiss and Taylor considered that the nylon fibers, by producing linear areas of liquefaction through the blood clot, provide orienting pathways across the gap for the regenerating nerve fibers and thus prevent whorling and neuroma formation. Their method has met with success in smaller animals, rats and cats.

VINYL RESINS

The use of plastics referred to as "Vinylite" is occasionally reported. This is one of the trade names employed to describe a variety of manufactured products varying from polyvinyl alcohol to a polymerized mixture of vinyl chloride and vinyl acetate. These substances are often mixed with a plasticizer to give them pliability, and an almost limitless number of materials can be compounded under the term "Vinylite." Few reports of the actual use of vinyl compounds within the body have appeared. It would be only a coincidence if two investigators used the same chemical compound, since this product is a highly variable one.

Bailey and Ford⁵¹ report that a Vinylite compound buried in the abdominal wall of guinea pigs caused only slight tissue reaction. MacQuigg⁵² used a vinyl chloride polymer in the form of a tube for prolonged intramuscular injections. Such tubes were left in place up to four days without apparent reaction. Narat and Cipolla⁵³ found that a vinyl derivative called "Tygon" inactivated penicillin when kept in contact with it for twenty-four to seventy-two hours. There was a 38 per cent deactivation of the penicillin in seventy-two hours, and the same inactivation was observed with rubber tubing. It was suggested that either this material not be used for the administration of penicillin or that the dosage given through it be correspondingly increased. Whether shorter periods of contact between the tubing and the penicillin deactivated the latter was not recorded.

The vinyl compounds have found extensive use in the formation of prostheses in plastic surgery^{54, 55} and in forming protective layers over the skin, as around ileostomies and colostomies.⁵⁶ There is a reasonably large group of papers on this phase of the subject, but since this is not strictly related to the use of plastics within the body, no effort has been made to review this literature.

(To be concluded)

likelier to clot rapidly in plastic tubes than in vein grafts for vascular anastomosis, although the use of plastic tubes, if satisfactory, would be a simpler technical method

Edds⁴⁰ published a description of a method of preventing neuroma formation in severed peripheral nerves by coating the proximal end of the nerve with a 10 per cent solution of methyl methacrylate in acetone. This was successful in the nerves of rats up to a diameter of 1.5 mm, but it was not applied extensively to larger nerves. It was suggested that to make the procedure effective in larger nerves, the epineurium must be retracted from the end of the nerve before the acetone and methacrylate are applied.

NYLON

"Nylon" is a generic term applied to a large family of related chemical compounds and not to a single pure product. This large group of chemical compounds consists of polymeric amides whose molecular structure is made up of alternate groups of NH-CO and CO-NH with a variable number of interposed methylene groups.⁴¹ Chemically, they resemble natural proteins. Nylons are used widely as filaments to fabricate a variety of products, such as stockings and parachutes. They are thermoplastic, and although they soften at a higher temperature than most thermoplastic substances, they can be readily extruded or molded into various forms. It is in the form of a filament that nylon plastics have been utilized in surgery, specifically in the form of suture material.

Since the term "nylon" refers to a large group of chemically related but structurally different compounds, it is obvious that to discuss the use of nylon in surgery, one should know exactly what chemical compound is used in each product so labeled. This is difficult because, as in some other plastics discussed below, commercial secrets prevent general knowledge of the detailed composition of individual products. In practice, nylon in the form of filaments of various sizes is supplied to medical supply houses, which take the responsibility of dispensing the material in desirable forms. They also take the responsibility of furnishing to those who use the material a nylon filament that by previous experimental study has been found suitable. Whether one medical supply house dispenses nylon sutures identical with those dispensed by any other supply house is not known. The same criticism might be leveled against catgut, silk or cotton, whose exact structures surgeons do not know but which are used because the same product has been found satisfactory year after year.

Nylon, using the term as applied to surgical suture material, is odorless, tasteless and resistant to most chemicals, and withstands repeated autoclaving without weakening of its innate toughness and elasticity. It does not deteriorate significantly with

age, is not absorbed when buried in human or animal tissues and is extremely strong. A strand of nylon compared to a strand of silk of the same size has been found by Nichols and Diack⁴² to be stronger, more elastic and more resistant to moisture absorption.

Nylon can be supplied as either a monofilament or a braided suture. Melick,⁴³ Haxton⁴⁴ and Arnes⁴⁵ have reported studies comparing the two forms of suture. It seems generally agreed that the monofilament causes slightly less tissue reaction than the braided form of multifilament material, but is harder to handle and more difficult to tie in knots that will not slip. In point of fact, the criticism of slipping of knots tied with nylon has been directed against the braided form as well as the monofilament. Unless sutures are tied carefully, particularly with the larger sizes of nylon, there seems to be more tendency to slip than when silk sutures are used.

Clinical trials of nylon as a suture material have appeared in the literature in reports by Stonham,⁴⁶ Haxton⁴⁴ and Burman.⁴⁷ All these authors have recommended nylon as superior to silk or any other suture material for general use.

Experimentally, adequate studies of nylon as a suture material have been made by several investigators. Melick⁴³ reports that in the early stages of healing there is more reaction around nylon multifilament sutures than around silk but that the final result is the same, neither suture material showing any significant tissue reaction compared to that caused by catgut. Arnes⁴⁵ observes that nylon causes less reaction than silk and that in infected wounds, leukocytes are found around silk longer than around nylon. Nichols and Diack⁴² state that the reaction to silk and nylon is about the same, but they favor the latter because of its greater tensile strength.

It is not known whether these various workers, who obtained the material with which they experimented from different supply houses, employed the same chemical product, but their results agree so closely that one can only conclude that there is minimal tissue reaction to the nylon sutures generally used. In an extensive study of wound healing, Localio, Casale and Hinton^{47, 48} tested the strength of wounds in rats sutured with catgut, cotton, steel-alloy wire, silk and nylon. They found nylon equal to cotton, steel wire, and silk, and better than catgut. Their figures indicated there was slightly more rapid firm union with nylon than with any of the other sutures, but the rate of healing with all the non-absorbable sutures tested did not vary enough to be statistically significant.

Burman⁴⁹ has reported a series of 4 cases of arthroplasty of the small joints of the finger with so-called "parachute nylon" as an interposition membrane. Only 1 of the cases was reported in detail, and the patient was considered greatly im-

an amount from 250 to 1300 cc daily. The urinary output ranged between 750 and 250 cc daily. Retrograde pyelogram on the twelfth hospital day showed nothing unusual. The urine was sterile on admission, but later a moderate number of and abundant colonies of colon bacilli were grown respectively from the right and left ureteral specimens. On the fifteenth day a bromsulfalein test showed 22 per cent retention of the dye after forty-five minutes. With the constant vomiting the patient's condition grew worse. A questionable pericardial friction rub was heard. The temperature ranged between 99 and 100°F during the entire admission. The patient was found dead on the twentieth hospital day.

DIFFERENTIAL DIAGNOSIS

DR EARLE M. CHAPMAN: May I see the x-ray films?

DR RICHARD SCHATZKI: So far as the kidneys are concerned I should say that in the intravenous pyelogram they are a little enlarged. Some of the films show a small amount of dye in the kidney pelvis. The surprising thing to me about the intravenous pyelogram is that there is any dye visible with specific gravities of the urine of only 1.008 and 1.011. The retrograde pyelogram shows that the kidneys are normal in size and shape. The area of calcification mentioned is on the left side and shifts around inside the abdomen. The chest shows a small area of either atelectasis or scar in the posterior lower aspect of the left lower lobe, with a small amount of fluid in this area. The few stomach films that we have show a deformity that is by no means characteristic, and I thought that it would be wise to look at the x-ray report made at that time and found that the examination had been unsatisfactory. The examiner could see the patient only in the horizontal position. The deformity involves the antrum as well as the immediate postpyloric region. I cannot see any tumor mass in the stomach, nor can I be sure whether or not there is an ulcer present, but my impression, along with that of the fluoroscopist, is that no ulcer is visible.

DR CHAPMAN: I think that you will agree with me that this is, indeed, a case in which it is going to be difficult to come out with a diagnosis that covers the syndrome. There are one or two questions that I think fair to have answered from the record. It seems to me that there must have been some comment during a nine-week illness whether this woman's bowels moved, especially while she was in the hospital.

DR TRACY B. MALLORY: They did.

DR CHAPMAN: And I should like to take a quick look at the electrocardiographic tracings. The ST segments in all leads were sagging, and the T waves in Leads 1 and 3 were inverted. I am looking also at the P waves to see if they were inverted, since the right and left arm electrodes may have been mixed; it could have been a technical error.

We can discuss first the more probable diagnoses in this patient and then those that are speculative and put them together to try to explain this woman's death in renal failure, with a low nonprotein nitrogen. It is stated in the record that she appeared far sicker than the temperature or the nonprotein nitrogen indicated. Indeed she was. She died without any indication of the true diagnosis by the laboratory and other investigative procedures.

The patient had had rheumatic fever, that brings up the question, Did she have rheumatic heart disease and attendant disorders? I believe that there is not enough evidence in this record to establish rheumatic heart disease or heart failure in the final illness as having been responsible for death. At the age of thirty-seven the patient had a hysterectomy—in other words, injury to the pelvis of a surgical nature. X-ray study revealed an area of old calcification, although its duration was not known, lying apparently on the left side in the region of the left kidney. That suggests an old healed tuberculous lesion of many years' duration.

We then come to the illness of nine weeks' duration characterized by weakness, edema of the lower extremities, severe nausea and finally almost constant vomiting. The gall bladder had been removed for these symptoms, but I believe that this was an unnecessary operation—it was done in good faith but did not relieve the patient. It was following this that she had the first episode that I believe was the first clue to what was wrong. I interpret these signs and the sudden onset of pain in the lower left chest as having been due to a large pulmonary infarction. Indeed, we know that the first pulmonary infarct usually slithers into the left lower lobe, it has been pointed out by Allen, Linton and Donaldson¹ that 70 per cent are found in the left lower lobe. In support of this diagnosis is the persistence of the physical signs despite the treatment with penicillin, which was given on the basis, I suppose, of infection. In further support, I think that the electrocardiographic changes were similar to those that are seen in the presence of pulmonary infarction. They were not entirely typical because in acute pulmonary infarction changes in the S waves are described. This tracing is abnormal but not diagnostic of any particular type of heart disease, although it does suggest obstruction of the pulmonary artery.

The final consideration is the renal failure. What type of renal failure was this? Why did the patient die in this peculiar manner? I think that the presence of large kidneys demonstrated by Dr Schatzki excludes glomerulonephritis or any other type of chronic process. I cannot believe that this was amyloid disease because no chronic infectious process was demonstrated. Immediately, one wonders if at operation done outside this hospital some form of sulfonamide was dusted into the wound, whether this was a sulfathiazole reaction in the kidney, and whether these were toxic kidneys.

CASE 33101

PRESENTATION OF CASE

A forty-seven-year-old housewife entered the hospital complaining of pain along the left costal margin

Nine weeks before admission the patient had consulted a physician because of fatigue, swelling of the feet and ankles, vomiting and epigastric pain. The pain was intermittent, usually occurring after fatty or fried foods or cabbage had been eaten. It was sharp, lasted a few minutes and was most marked at the left costal margin, occasionally radiating medially into the epigastrium. It was aggravated by inspiration and by the attacks of vomiting, which usually occurred once a day about thirty minutes after a meal. The patient was given digitalis and sent home to bed. During the following week the ankle swelling subsided, but the other symptoms persisted. Seven weeks before admission a fibrous, contracted gall bladder containing a single stone was removed at another hospital. Ten days later the patient felt a sharp pain in the left lower chest and developed dyspnea and physical and x-ray signs of consolidation of the left lower lobe of the lung. The temperature and pulse were elevated. The symptoms persisted despite penicillin injections. Seventeen days before entering the Massachusetts General Hospital, she went home against advice. At home she felt feverish and anorexic, but noted no chills, petechiae or edema.

At the age of fourteen years an attack of fever and joint pain had kept the patient in bed about four weeks. At the age of thirty-seven she underwent a hysterectomy.

Physical examination revealed the patient to be pale and apparently acutely ill. The tongue was red and smooth, and the skin rough and dry. The apical beat was regular at a rate of 110. A Grade I systolic and a questionable presystolic murmur were

heard at the apex. There were dullness, decreased breath sounds and decreased tactile fremitus at the base of the left lung posteriorly. The entire right side of the abdomen felt resistant. At the upper pole of the vertical scar in the right upper quadrant there was a draining sinus. An old healed scar occupied the midline above the symphysis. There was slight pitting edema of both ankles.

The temperature was 99.6°F, the pulse 105, and the respirations 26. The blood pressure was 140 systolic, 70 diastolic.

Examination of the blood disclosed a red-cell count of 2,400,000, with a hemoglobin of 10 gm per 100 cc, and a white-cell count of 21,000, with 82 per cent neutrophils and 16 per cent lymphocytes. The specific gravity of the urine varied between 1.008 and 1.011. The urine gave a +++ to ++++ test for albumin, and the sediment contained innumerable granular casts but no cells. The blood nonprotein nitrogen was 41, the phosphorus 5.5 and the sugar 88 mg per 100 cc, the total protein was 6 gm per 100 cc with an albumin of 2.45 and a globulin of 3.55 gm, and the carbon dioxide 24.2 milliequiv per liter. An electrocardiogram showed a rate of 138, with a PR interval of 0.18 second, slurred QRS complexes, sagging ST segments in Leads 1, 2 and 3, diphasic T waves in Leads 2, CF₁ and CF₄, inverted T waves in Leads 1, 3 and CF₁ and sagging ST segments in Leads CF₁, CF₄ and CF₆. On x-ray examination the heart was somewhat globular, and the cardiothoracic ratio was 12.5:26.0. On the left the posterior portion of the diaphragm was elevated, and there was a hazy area of increased density in the left side of the chest posteriorly, with a few linear areas of increased density extending upward obliquely from the diaphragm. A barium meal demonstrated slight deformity of the antrum and prepyloric area and enlargement and deformity of the duodenal cap without ulceration. In the intravenous pyelogram the kidneys appeared large. The dye was poorly excreted, and only on the right were faintly outlined calyces visible. There were several calcified nodules opposite the third lumbar vertebra.

In the hospital the patient was lethargic and almost constantly nauseated, appearing far sicker than the temperature or the nonprotein nitrogen warranted. All food was vomited. A duodenal tube was inserted, but vomiting continued, varying

nary emboli. There was a localized peritonitis in the lesser peritoneal cavity, but we found nothing intrinsically wrong with the stomach or duodenum. The posterior surfaces of both the stomach and the duodenum were bathed in pus from this localized peritoneal abscess. The kidneys, as Dr Schatzki predicted, were enlarged. Microscopically they showed a rather extensive fatty vacuolization of all the proximal convoluted tubules—a lesion that is consistent with the severe albuminuria that this patient had. The liver also showed rather marked fatty vacuolization, particularly at the periphery of the lobules—the type of vacuolization that is seen in patients with starvation, it might be attributed to the vomiting for a period of several weeks.

DR. CHAPMAN: Were these changes consistent with amyloid disease in the kidneys? I mentioned that as possibly occurring secondary to an infection.

DR. MALLORY: There was no amyloidosis. Anatomically, we must call this lesion lipid nephrosis, although the clinical picture was somewhat unusual.

DR. CHAPMAN: How about the heart?

DR. MALLORY: It was entirely normal, weighing 260 gm. There was a calcified tuberculoma of the spleen.

CASE 33102

PRESENTATION OF CASE

A twenty-eight-year-old Italian housewife was admitted to the hospital because of easy fatigability.

The patient stated that she had felt tired for three weeks. This fatigability was associated with some dizziness, occasional faintness and nausea and vomiting. She had had no cough, the menstrual flow had diminished recently, and she had missed one period. She had had no other vaginal bleeding.

Because of rheumatoid arthritis she had been admitted to this hospital seven years previously and had subsequently been followed in the Out Patient Department. Four years before the previous admission an appendectomy and a removal of an ovarian cyst had been performed in another hospital.

Physical examination revealed a thin, pale woman with spindling of most of the fingers and thickening of the tissues around the right knee. The blood pressure was 105 systolic, 45 diastolic, and there was a Grade I systolic murmur at the apex.

Examination of the blood disclosed a red-cell count of 2,000,000, with a hemoglobin of 5.8 gm and a hematocrit of 20, and a white-cell count of 2800, with a normal differential. The urine was normal. Several stools were guaiac positive. A gastric analysis revealed no free hydrochloric acid either

before or after histamine, with 5 units of combined acid in each specimen. Plain films of the chest and abdomen were normal.

Two days after admission the white-cell count rose to 5500, without change in the red-cell count. A gastrointestinal series and barium enema were negative except for slight deformity of the stomach opposite the incisura, somewhat suggestive of an ulcer on the posterior wall. A blood count done shortly after admission revealed 4.5 per cent reticulocytes. Liver-extract therapy was instituted two weeks after admission, and three days later the reticulocytes had risen to 6.6 per cent. On the fourth and fifth days, however, they had fallen to 4 and 3 per cent respectively. The red-cell count rose slowly, and about three weeks after admission it had reached 3,200,000, with a hemoglobin of 9.5 gm. Because of the deformity of the stomach visible on the x-ray film, a gastroscopic examination was done about two weeks after admission, revealing normal peristaltic waves and a normal pylorus. Throughout the body of the stomach, from just distal to the angulus almost to the cardiac orifice, involving the lesser curvature, posterior wall and greater curvature, the rugae were unusually thick and tortuous and presented a definitely rigid appearance, with some areas of reddening and some mucosal hemorrhage. These folds did not flatten by air inflation. Along the greater curvature and posterior wall the mucosa had a verrucous appearance. The anterior wall appeared essentially normal except for reddening. There was no blood in the stomach, and no ulceration or erosion.

Approximately a month after admission an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. BERNARD JACOBSON: We are told that this young woman had had definite rheumatoid arthritis at least seven years previously and that when admitted to the hospital she had deformities consistent with long-standing rheumatoid arthritis. From this point on, however, I shall give no further thought to the rheumatic condition, I do not believe that it was related to the present disease. We are not told whether she noticed melena. This is interesting but does not rule out a history of bleeding before admission. Of course, the symptoms of dizziness, faintness and easy fatigability are common to many diseases. In this case we can readily ascribe them to the nonspecific effects of anemia in general. We are told that the patient had missed one menstrual period. We are not told anything about the results of a pelvic examination. In view of this I shall assume that the pelvic examination was essentially negative and that the patient was not pregnant. Any severe anemia can temporarily produce amenorrhea. At the time of admission the blood pressure was 105 systolic, 45 diastolic—a rather low pressure that is consistent with the evidence of anemia.

A more probable explanation and one that seems to fit is that this woman had extensive thromboses in the venous channels leading up into the abdomen, finally going past the left renal vein, which is the lower tributary, and finally involving the right renal orifice. What supports this extremely rare diagnosis? She had renal failure, with large kidneys, anemia, fixation of the specific gravity, the presence of a large amount of albumin, granular casts, a high blood phosphorus and a high nonprotein nitrogen — I assume that the nonprotein nitrogen rose later on.

DR MALLORY It subsequently went to 54 mg per 100 cc.

DR CHAPMAN. The record states that the patient was vomiting and excreting between 750 and 250 cc of urine. We know that a fall in the urinary output below 500 cc is not compatible with long life. In fact, when the output falls below 500 cc a day few people can survive longer than ten days. At the end a pericardial friction rub developed, which is typical of patients dying in uremia. Along with this a test of liver function showed 22 per cent retention of the dye. My interpretation of this test is that there was an extensive toxic liver injury from venous thrombosis.

All through the record it states that the patient was vomiting, and an attempt was made to diagnose some disease of the gastrointestinal tract, either ulcer or obstruction, and yet apparently she did not have either. One clinical sign was pointed out to me by Dr Schatzki years ago — namely, that in patients who have severe nausea, along with vomiting, one should look for the primary disease outside the digestive tract. I think that that may have been true in this case. The patient had severe nausea and vomited continuously, and yet all the studies failed to reveal disease in the digestive tract and she did not have obstruction because the bowels moved while she was in the hospital. But what was the source of the nausea?

There is one other point that I should refer to — namely, the signs over the left lower lobe, which I attributed to pulmonary infarct.² The record states that there were dullness, decreased breath sounds and decreased tactile fremitus at the left base, these signs would also fit with a process causing occlusion of the bronchus — in particular, carcinoma. There could have been cancer within the abdomen, either primary or secondary to this lesion, but I think that that is an unlikely diagnosis and mention it only in passing.

In conclusion, I believe that this patient had had rheumatic fever — but not rheumatic heart disease — and no evidence of congestive heart failure. She had had a previous operation on the pelvis. She had calcification in the abdomen suggesting old tuberculous lesions and finally an illness with swelling of the legs, nausea and vomiting that led to death within nine weeks and during which the gall bladder, which I believe was not the cause of the ill-

ness, was removed. The only way I can explain the whole picture is by extensive venous thrombosis leading higher and higher, reaching the level of the tributaries of the renal veins and thus giving the picture of a terminal renal failure.

DR SCHATZKI I may have given the wrong impression about the deformity near the pylorus. I do not know what it is from the film, but I think that there is something definitely wrong there and it may have been produced by ulceration, although no ulcer is demonstrable now.

DR CHAPMAN I interpret the changes as probably having been due to manipulation in that area during the gall-bladder operation.

DR SCHATZKI If that is true the reaction is the most unusual one that I have seen.

DR CHAPMAN There are no signs of obstruction?

DR SCHATZKI Not on the film, and the x-ray report does not mention it.

DR CHAPMAN That was a point I tried to clear up.

MR JAMES H AUSTIN With obstruction of the inferior vena cava, would you not expect the red-cell count to be higher, and how do you explain the bromsulfalein test that is recorded?

DR CHAPMAN I do not believe that the patient had independent liver disease. That test was late in the course. She died of renal failure, and that was part of the general toxic picture.

DR LEWIS W KANE Could the x-ray film be interpreted as showing a lesion in the pancreas?

DR SCHATZKI I do not believe so. Offhand, I should say that the lesion was most probably due to a former ulcer.

CLINICAL DIAGNOSES

Chronic nephritis
Uremia

DR CHAPMAN'S DIAGNOSES

Injury from pelvic operation
Calcified tuberculous nodes left abdomen
Extensive venous thromboses ascending vena cava
Pulmonary infarction left lower lobe
Renal failure from venous obstruction

ANATOMICAL DIAGNOSES

Subdiaphragmatic and subhepatic abscess, secondary to cholecystectomy
Acute lipoid nephrosis
Fatty vacuolization of liver
Healed tuberculosis of spleen

PATHOLOGICAL DISCUSSION

DR MALLORY The trouble was not above the diaphragm, as Dr Chapman suggested on the basis of pulmonary infarcts, but beneath it. There was a large subdiaphragmatic abscess, and the only thing we found in the pleural cavity was fairly dense pleural fibrosis at the base. There were no pulmo-

the likeliest form of tumor, if it was a tumor. The preoperative diagnosis of lymphoma is almost impossible to make either by x-ray study or gastroscopy. I have made it correctly in one case in which the pathologist on the gross appearance did not believe that lymphoma was present, but the microscopic sections proved it to be lymphoma. I was probably lucky because I have been wrong since then.

DR TRACY B MALLORY: Dr Ropes, have you any comment?

DR MARIAN W ROPES: We followed this patient for a good many years, and so far as the arthritis was concerned she was doing well. The anemia came on rapidly over a period of several months. We are still entirely unable to explain the anemia. She apparently had a spontaneous remission before treatment was started and the blood picture returned to a fairly normal level. We all decided that there was probably no intrinsic disease in the stomach. The guaiac tests on the stools were only slightly positive at the time when iron therapy was being given. Whether there was major bleeding from the stomach was a question, we thought that there was none.

A PHYSICIAN: I should like to ask Dr Benedict if he would expect to visualize the crater-like fleck by gastroscopy if the lesion was on the posterior wall of the stomach.

DR BENEDICT: I should, but I did not.

CLINICAL DIAGNOSIS

'Malignant lymphoma of stomach'

DR JACOBSON'S DIAGNOSES

Simple anemia due to gastric bleeding
Malignant tumor of stomach
Rheumatoid arthritis

ANATOMICAL DIAGNOSIS

Chronic pancreatitis, with extension to wall of stomach

PATHOLOGICAL DISCUSSION

DR MALLORY: I do not know whether the operative findings or the pathological report is going to be entirely satisfying in this case. There was no tumor in the stomach. When the patient was explored the posterior wall and lesser curvature of the stomach seemed thick and densely adherent to the pancreas. Frozen section at the time of operation showed no tumor, and that fact was later confirmed by the final sections. There was a severe, extensive chronic pancreatitis, with marked adhesions to the stomach wall, but I was unable to make a diagnosis of gastritis. The stomach of any adult person, of course, always shows histologically some degree of inflammation. It has often been spoken of as physiologic gastritis. If this later becomes exaggerated in character, such as that frequently seen in association with ulcer, a picture results that the

gastroscopist describes as hypertrophic gastritis. In this case I do not believe that the inflammatory process was beyond the normal limits. Also, there was no suggestion of atrophic gastritis, the glands were well formed and contained normal numbers of chief and parietal cells. From the microscopic appearance I see no reason why the stomach was not secreting normal gastric juice.

DR BENEDICT: Some years ago Dr Mallory and I* checked up the histologic and gastroscopic findings in resected stomachs and found that we agreed fairly well regarding the presence of gastritis and the type. I think that this case, because of the severe pancreatitis, could throw off the gastroscopist and the roentgenologist. Do you agree, Dr Schatzki?

DR SCHATZKI: Yes.

DR MALLORY: I think that the deformity in the stomach was due to marked thickening of the external layers of the wall secondary to the adhesions of the pancreas.

DR JACOBSON: Is it possible to explain both the x-ray picture and the gastroscopic picture by edema?

DR MALLORY: It is difficult for us to judge edema in a resected specimen. It could, I am sure, disappear under some conditions. It could be produced by the surgeon's clamps on the stomach at operation. That is an unreliable observation on our part.

DR BENEDICT: There was an interval of two or three weeks between operation and gastroscopy. Do you regard that as important?

DR MALLORY: Considerable grades of acute gastritis can disappear rapidly. That is always a possibility.

DR JACOBSON: What do you think was the cause of the anemia?

DR MALLORY: I have no better guess than anyone else.

DR JACOBSON: I suggest that this patient be followed from the point of view of later development of pernicious anemia or atrophic gastritis. Achylia at the age of twenty-eight is not frequent and should be looked on as a basis for pernicious anemia, benign polyp or carcinoma.

DR BENEDICT: Do you think that it is the achylia gastrica or the gastric atrophy that leads to carcinoma? It is my belief that gastric atrophy leads to carcinoma—that gastric carcinoma does not develop in a healthy mucosa.

DR JACOBSON: This mucosa may not be healthy five years from now. Most people who eventually develop pernicious anemia are probably born with achylia gastrica.

DR BENEDICT: And atrophic gastric mucosa?

DR JACOBSON: I do not know.

DR BENEDICT: What about that, Dr Mallory?

DR MALLORY: I do not know how far back in youth one could see it. We do not often see atrophic gastritis in young persons.

*Benedict E B., and Mallory T B. Correlation of gastroscopic and pathological findings in gastritis. *Surg Gynec Obstet* 76:129-135, 1943.

The same thing holds true for the Grade I systolic blow at the apex. From the description of the blood counts it is obvious that this was a normocytic, normochromic anemia. We are told that the initial white-cell count was 2100, with a normal differential. We are further told that two days later the white-cell count rose to 5500. I rather discount the rise. I prefer to say that the white-cell count on admission was 2800 and two days later was found to be 5500. Accepting the statement that the differential count was normal and that there were no significant changes in the platelets or in the morphologic structure of the red cells, I think that we are forced to call this a nonspecific, simple type of anemia. We can fairly well rule out leukemia, although not completely. We can also rule out thrombocytopenia.

The roentgenologist's suggestion of an ulcer on the posterior wall of the stomach is important. It brings to mind a patient whom I followed some years ago with frank classic Addisonian pernicious anemia. He had no symptoms during four or five years of maintenance treatment, and then developed digestive symptoms that led to gastrointestinal studies, the report of the x-ray series was similar to that in the case under discussion, with the suggestion of an old healed ulcer. I am sorry that I did not evaluate the interpretation properly at that time. Instead of advising the patient to come to the hospital immediately I dillydallied, and three or four months later he presented himself with an inoperable adenocarcinoma. The fallacy of my reasoning, I hope, will not be repeated again, a patient with pernicious anemia and a patient with a long-standing achylia gastrica should never be given a diagnosis of ulcer. Something else should be suspected.

In the case under discussion, in view of the roentgenologic findings, we must definitely look for something other than ulcer in the patient's stomach. Apparently the service was of the same opinion.

Before liver was given the reticulocyte percentage was 4.5, which is definitely above normal. In view of the other findings I shall ascribe that to recent mild or moderate hemorrhage. Since we are told nothing about jaundice or yellow scleras, I assume that this was not a hemolytic anemia with a high reticulocyte count. The fact that a slight increase in reticulocytes occurred a few days after liver extract had been given has no significance. There is nothing in the abstract to suggest liver-deficiency anemia.

We are told that three weeks after admission the red-cell count was 3,200,000, with a proportional hemoglobin. This rise was undoubtedly consistent with the possibility that acute hemorrhage from the stomach had ceased and that a normal regenerative process was going on. Several years ago an interesting series of articles by a man named Schiødt*

in Copenhagen pointed out that a rise of the hemoglobin and the red-cell count in regeneration from bleeding peptic ulcer is similar to the elevation following the administration of liver extract in pernicious anemia and to that in hypochromic anemia after the administration of iron. In other words, the physiologic capacity of the bone marrow for regeneration is fairly uniform, and one can expect a person with normal bone marrow who stops bleeding to regenerate the blood as rapidly as a patient with pernicious anemia after liver extract.

Gastroscopic examination showed an area of submucosal hemorrhage. So far as I can see, this was a diffuse infiltrating lesion in the submucosa. It was entirely different from the atrophic, thin mucosa of pernicious anemia. There was nothing in the history to suggest alcoholic gastritis or other cause of severe hypertrophic gastritis.

Again assuming that the blood serologic findings were negative, we can probably dismiss syphilis of the stomach. We are therefore faced with a tumor of the stomach. In view of the extensive appearance of the gastroscopic findings I believe that this was not a benign but a malignant tumor of the stomach. The age—twenty-eight years—is not against the finding of such a tumor. The type of anemia, a simple normocytic normochromic anemia, is perfectly compatible with it. So far as the nature of the tumor is concerned I do not believe that it is in the province of anyone but the pathologist to tell. Lymphosarcoma is a good possibility in a woman of this age, if the tumor was an infiltrating carcinoma. Even leiomyosarcoma is possible. I shall therefore rest with the diagnoses of simple anemia due to hemorrhage from the stomach, malignant tumor of the stomach and old rheumatoid arthritis.

DR RICHARD SCHATZKI. The remark in the record about the x-ray findings may have given Dr. Jacobson the wrong impression about the actual appearance of the stomach. This patient's stomach at times looked perfectly normal, and, as this film demonstrates, at other times we thought that there was definite thickening of the mucosa in the region of the angle of the stomach. In this area of thickening there was something that was suggestive of ulcer. I was the examiner, and I was not too satisfied because the thickening disappeared easily—at times it was present, and at others it was not. I finally said that it was suggestive of ulcer. We thought that there was definitely something wrong with the stomach, and it was the X-ray Department that asked Dr. Benedict to do the gastroscopy.

DR EDWARD B. BENEDICT. The edema of the submucosa and the hemorrhage certainly meant acute gastritis to me, and the verrucous appearance of the mucosa meant chronic gastritis. The fact that the rugae were large and did not disappear with air inflation as they usually do suggested the possibility of lymphoma in a person as young as this—a diffuse process. I considered lymphoma

Controls shared with the fully treated group the experience of attendance at the clinic and of irradiation with the longer ultraviolet rays, for which no therapeutic effects have been claimed. Half the treated controls received in addition a maintenance dose of vitamin D.

Volunteers were allocated to the treated groups by random sampling. A comparison of the records of the groups treated with complete and long ultraviolet rays showed that the persons in the former did not differ significantly from those in the latter in respect to sickness and to the reported duration of colds. There was no evidence of a vitamin D deficiency in either group. Some subjects stated that their health had been better during the period of attendance in the clinic, but there was no evidence that this was due to the short ultraviolet rays, since the numbers were about equally distributed in the two treated groups.

The comparisons between the treated and untreated groups were not quite so clean cut probably because those in the latter could not be selected at random. The study showed that the treated group of clerical and factory workers fared no better than the untreated group in respect to absenteeism due to sickness. In respect to colds, there was actually a significant advantage to the untreated subjects. Both groups of treated miners, those receiving and those not receiving the shorter ultraviolet rays, had a significant advantage over the untreated controls in respect to sickness and total absences. Evidence, however, was given to show that the previous health of this untreated group had not been so good as that of the treated group in the previous year.

On the whole the results of the study may be interpreted as indicating that the general application of ultraviolet irradiation has none of the "tonic" effects that have been attributed to it. From this point of view, the use of artificial sunlight may be considered only as a sort of modern version of sun worship.

Dr. Colebrook's report, in addition to being a clear and careful presentation of this particular study, can also serve as a model for large-scale controlled therapeutic experiments. The methods employed in the study are presented in great detail and are critically analyzed, as are the data and the results. It should be borne in mind, however, that this study

was not concerned directly with the bactericidal action of ultraviolet light. That property, which requires ultraviolet rays of different wave lengths than those used for antirachitic irradiation, has been used in attempts to eliminate cross infections and bacterial contamination of surgical wounds. An evaluation of such uses for ultraviolet irradiation requires entirely different techniques.

NATIONAL EMERGENCY MEDICAL CARE

QUESTIONNAIRES are now being sent by the Committee on National Emergency Service of the American Medical Association to approximately 5000 physicians, selected at random, who remained in civilian practice during the war. Following a study of the replies that are received, it is expected that sound conclusions can be drawn regarding the medical care that the civilian population received during that period. Furthermore, it is hoped that intelligent opinions concerning the inadequacies that arose and how they could have been avoided will be expressed.

In view of the recent rapid advances in scientific warfare, as well as in scientific medicine, the House of Delegates of the American Medical Association, at its meeting in December, 1945, recognized that information concerning how the medical profession can best serve the military and civilian populations in the event of another national emergency must be made generally available, and the appointment of the Committee on Military Medical Service, whose name was eventually changed to the Committee on National Emergency Medical Service, was accordingly authorized. During December of last year questionnaires were forwarded to more than 50,000 former medical officers, requesting information regarding their experiences while in military service. The response was excellent, and these replies are now being analyzed and studied. The results of this study combined with those arising from an analysis of the replies to the present questionnaire should permit the drafting of recommendations that would be of inestimable value to the people of this country if another emergency should arise in the near future.

Since the present questionnaires are being sent to only a small percentage of the physicians who

ARTIFICIAL SUNLIGHT TREATMENT IN INDUSTRY

EVER since Finsen in Denmark and Rollier in Switzerland popularized the use of natural and artificial sunlight in the treatment of nonpulmonary tuberculosis, tremendous interest in the possible general helpful effects of this form of treatment has been manifested both by the medical profession and by the general public. This interest increased still more after it was demonstrated that exposure of the skin to ultraviolet rays was effective in preventing infantile rickets and when this effect was shown to be due to the conversion of the ergosterol present in the skin into vitamin D by the irradiation.

Ultraviolet irradiation has been widely used in the treatment of certain diseases, but it has also

been recommended on less secure grounds both as a general "tonic" and as a means of preventing and correcting minor conditions of ill health. The increased use of artificial light in work places and the black-out conditions prevailing in many localities during the war years encouraged the prophylactic use of sources of artificial sunlight in factories, mines and offices. There is no convincing evidence, however, of the value of such uses for ultraviolet irradiation. It has been claimed that a few minutes' exposure to the rays of a quartz mercury-arc lamp each week is equivalent to some hours of natural sun bathing. From this has arisen the far more reaching claim that a course of such exposures reduces the amount of absenteeism due to accidents, common colds and general ill health.

It is now a simple matter to administer ultraviolet treatment to large numbers of workers with a relatively small loss of working time, and it would be quite easy to apply such therapy to large proportions of the employees in industrial and other occupations were it actually proved to have the good general effects attributed to it. In view of the conflicting nature of the previous evidence on the subject, the Industrial Health Research Board of the Medical Research Council of Great Britain considered it highly desirable to sponsor a well controlled and relatively large-scale inquiry into this important subject. The study was carried out by Dr Dora Colebrook, and her excellent report was recently published*.

The effects of ultraviolet irradiation on the health of clerical and industrial workers in three separate communities were investigated in Great Britain during the winter of 1944-1945. The criteria used were as follows: the amount of absenteeism due to sickness in all the groups, the duration of colds among clerical and factory workers and the absenteeism due to injuries and other causes among miners. In each community the group of persons receiving the full range of rays from mercury-arc lamps was compared with two control groups—a treated group irradiated with lamps of the same type but from which the shorter ultraviolet rays were cut off and an untreated group. The treated

remained in civilian practice, it is obvious that practically all of them must be answered if a broad representation of facts, experiences and opinions is to be obtained. Every physician who receives the questionnaire should fill it out promptly and return it immediately, whether or not he signs his name is optional.

MASSACHUSETTS MEDICAL SOCIETY BUREAU OF CLINICAL INFORMATION

All secretaries of various medical groups, such as special societies and alumni associations, are requested to notify the Bureau of Clinical Information regarding scheduled meetings, annual dinners and so forth. If such data are on file, it is hoped that duplication of dates can be avoided.

DEATHS

CALDICOTT—Francis S. Caldicott, M.D., of Lowell, died January 17. He was in his fifty-eighth year.

Dr. Caldicott received his degree from Tufts College Medical School in 1913.

His widow survives.

KINGSLEY—Frederick Kingsley, M.D., of Chestnut Hill, died February 1. He was in his sixty-seventh year.

Dr. Kingsley received his degree from Queens University Faculty of Medicine, Kingston, Ontario, in 1905. He was a fellow of the American Medical Association.

His widow, two sons and a daughter survive.

NOBLE—Mary E. G. Noble, M.D., of Brookline, died February 16. She was in her seventy-fifth year.

Dr. Noble received her degree from Tufts College Medical School in 1902. She was psychiatrist at the Boston State Hospital for thirty-eight years, and was a member of the New England Society of Psychiatry and the Massachusetts Psychiatric Society.

Two nieces and a nephew survive.

PATCH—William T. Patch, M.D., of Roxbury, died February 7. He was in his eighty-sixth year.

Dr. Patch received his degree from New York University Medical College in 1890. He was a fellow of the American Medical Association.

RICHARDSON—Mark W. Richardson, M.D., of Newton Center, died February 12. He was in his eightieth year.

Dr. Richardson received his degree from Harvard Medical School in 1894. For a number of years he was a member of the former State Board of Health, and until his retirement several years ago he had served as medical director of the Equitable Life Insurance Company. He was a member of the Association of American Physicians and a fellow of the American Medical Association.

A son and three daughters survive.

ROSE—Wilfred A. Rose, M.D., of Lawrence, died September 24. He was in his forty-second year.

Dr. Rose received his degree from Tufts College Medical School in 1930.

His widow, a son and a daughter survive.

17 Diseases, Nutrition and Metabolism By Erich Urbach, D. With the collaboration of Edward B. LeWinn, M.D., cloth, 634 pp., with 266 illustrations and 112 tables. New York: Grune and Stratton, 1946. \$10.00.

English-speaking dermatologists owe the author a debt of gratitude for this stupendous encyclopedia of thirteen hundred references on the various aspects of nutrition and cutaneous metabolism. The book is divided into four parts. Part I deals with the influence of nutrition on the physiology of the skin. Part II describes the nutritional causes of dermatoses. The influence of diseases of the gastrointestinal tract, liver and pancreas on the skin is the subject matter of Part III. In Part IV the nutritional therapy of skin diseases is reviewed. There are over one hundred tables, in which are included many useful diets. The two hundred and sixty-six illustrations are excellent.

The compilation of the information so essential to the investigator and dermatologist required limitless patience and energy. This, however, is a fact familiar to those who have known the author for the past twenty years and who have read his writings in numerous journals. The volume should be a stimulus for further research in this somewhat neglected field of cutaneous medicine. The average dermatologist has little faith in the value of dietary therapy. Perhaps this is due to his lack of knowledge, or to disappointment in his results after following the enthusiastic recommendations of Dr. Urbach and other workers in this field.

All dermatologists and students of nutrition should have this book in their library, for they can use it with discrimination. Because of its many theoretical contraindications, however, the reviewer hesitates to recommend it to the student and general practitioner, unless he has had excellent basic training in biochemistry.

1 History of Medicine By Douglas Guthrie, M.D., F.R.C.S. (Edin.), F.R.S.E. With an introduction by Samuel C. Harvey, M.D. 8°, cloth, 448 pp., with 72 plates. Philadelphia: J. B. Lippincott Company, 1946. \$6.00.

This book appeared in England and on this side of the Atlantic at about the same time. In England it was put out by Thomas Nelson and Sons, whereas in the United States its publisher bears a different name. Yet, so far as can be ascertained, the two imprints are identical in pagination, illustrations and content.

The *British Medical Journal*, the *Bulletin of the History of Medicine*, the *Journal of the Association of American Medical Colleges* and the *Lancet* have reviewed this work. All but the *Bulletin of the History of Medicine* gave high praise to what the author had attempted and his manner of work, the review in the *Bulletin* is more critical and seems a trifle capricious.

As a matter of fact, this lively history of medicine from its earliest days to the present is readable, informative and entertaining. Although a professional historian can easily pick flaws in a work of this character, the ordinary reader will have little cause for complaint. The material is presented in an orderly way and is well indexed, the typography is good, the illustrations are apt, the literary style is admirable, and at the end of each chapter is listed a selection of material for further reading on the topic under discussion, so that earnest amateurs are well guided.

The book was placed on the shelf in one of the medical-school libraries along with several other books of current interest. The reaction of the students was unusual: a great many looked through the volume and glanced at the pictures, several sat down to read the book seriously, so that it was difficult to keep it in place, and a few wished to know how to obtain copies for themselves, saying that it seemed exactly the type of medical-history text for which they had been seeking. Such an opinion from students is about as complimentary as possible. On the whole, a taste for medical history develops late, and thus any well written book on the subject that attracts medical students commands respect. It may prove to be the cornerstone to many young people for years of pleasure.

The Ocular System. A handbook of roentgen diagnosis By Vincent W. Archer, M.D. 8°, cloth, 320 pp., with 148 plates. Chicago: The Year Book Publishers, Incorporated, 1945. \$5.50.

This handbook of roentgenologic diagnosis is a mine of useful information. It describes and shows in excellent illus-

trations the usual lesions found in the bones of both children and adults. The author states in his preface that the book is written for the occasional roentgenographer. In this, he achieves his purpose admirably. The book is well arranged, one does not need to search the index. The descriptions are concise and clear, and the reproductions of the x-ray films are almost without fault. Here is a good book both for the student and the experienced roentgenologist. It can be heartily recommended as the best handbook in its field.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Synopsis of Gynecology. Based on the textbook, *Diseases of Women*, by Harry S. Crossen, M.D., consulting gynecologist, Barnes, St. Louis Maternity and St. Luke's hospitals, and Robert H. Crossen, M.D., assistant professor of clinical gynecology and obstetrics, Washington University School of Medicine, assistant gynecologist and obstetrician, Barnes and St. Louis Maternity hospitals, and gynecologist, St. Luke's and DePaul hospitals. Third edition. 12°, cloth, 253 pp., with 132 illustrations. St. Louis: C. V. Mosby Company, 1946. \$3.00.

This third edition of a standard manual has been revised to date, and a new short chapter on medicolegal problems has been added, as well as many new illustrations.

The 1945 Year Book of Industrial and Orthopedic Surgery. Edited by Charles F. Painter, M.D., orthopedic surgeon, Massachusetts Women's and Beth Israel hospitals, Boston. 12°, cloth, 432 pp. Chicago: The Year Book Publishers, 1946. \$3.00.

This latest edition of a standard yearbook has expanded to some extent the amount of space allotted to industrial medicine and surgery. This volume should prove of value to all persons interested in orthopedic surgery and industrial medicine.

Transactions of the American Gynecological Society. Vol. 68, for the year 1944. Edited by Howard C. Taylor, Jr., M.D. 8°, cloth, 324 pp. St. Louis: C. V. Mosby Company, 1945.

This volume contains the various papers read at the annual meeting of the American Gynecological Society, held in June, 1944, in Hersey, Pennsylvania.

Virus as Organism. Evolutionary and ecological aspects of some human virus diseases. By Frank M. Burnet, M.D., F.R.S., director, Walter and Eliza Hall Institute of Research in Pathology and Medicine, Melbourne, Australia. Harvard University Monograph in Medicine and Public Health, No. 8. 8°, cloth, 134 pp. Cambridge: Harvard University Press, 1945. \$2.00.

This monograph is an expansion of the Dunham Lectures given at Harvard University in 1944. The author discusses some of the more important diseases of man from a consistently biologic point of view. Dr. Burnet's basic interpretation of virus disease is that viruses of micro-organisms have evolved by parasitic degeneration from larger micro-organisms, many of them in all probability from bacteria. The viruses survive by biologic reproduction, and the virus species, like any other living species, has found a way of indefinite survival. Dr. Burnet concludes that there is no escape from the pragmatic necessity of regarding viruses as living organisms reproducing their kind and subject to the same imperative of continued survival in a changing environment as other organisms. The first chapters consider the reproduction, variation and survival, evolution and change in virus disease, and the reaction of the host to virus infection. Following this there is a discussion of herpes simplex, poliomyelitis, psittacosis, smallpox, alastrim, vaccinia, yellow fever and influenza. A selected bibliography is appended to the text. This monograph, as well as all the other Harvard medical monographs, should be in all medical and public-health selections.

MASSACHUSETTS DEPARTMENT
OF PUBLIC HEALTHBLOOD GROUPING AND Rh TYPING
OF PRENATAL BLOODS

For the present, the Massachusetts Department of Public Health has facilities for blood grouping and Rh testing of a limited number of prenatal bloods submitted by physicians

Each specimen must be accompanied by the form entitled "Request for Prenatal Blood Grouping and Rh Typing" that is properly filled in. These forms, which include directions, may be secured from the Wassermann Laboratory, 240 Longwood Avenue, Boston 17. The specimen is submitted in the department's regular Wassermann outfit, and the blood-grouping, the Rh-typing and the prenatal Hinton test can be conveniently performed on the same specimen

BOOK REVIEWS

Public Health the American Way By H. B. Anderson 8°, cloth, 238 pp. New York: Citizens Medical Reference Bureau, Incorporated, 1945. \$2.50

This volume is a compilation of short abstracts interspersed with statements by the author, who is secretary-treasurer of the Citizens Medical Reference Bureau, Incorporated. The purpose of this bureau is stated in its certificate of incorporation: "To preserve, establish, maintain and safeguard through publicity and other lawful means, the right of adults or, in the case of minors, the right of parents or guardians to determine the form or manner of treatment or care to be prescribed or applied for the cure or prevention of disease."

Although some of the quotations in the book are of recent origin and from prominent physicians, others are not. The following are excerpts:

for all practical purposes smallpox of a virulent character in the United States is an imaginary disease the presence or absence of classical or virulent smallpox bears no relation whatever to the vaccination laws of any country but it does bear a direct relationship to the progress of the respective countries in the improvement of sanitary and general living conditions. Many persons have learned how to live so that to them it is natural to be healthy without the aid of medical products of any kind and they want to be left alone so they can continue to be naturally healthy.

It is doubtful whether this book will be of interest to many members of the medical profession.

The Principles and Practice of Tropical Medicine By L. Everard Napier 8°, cloth, 917 pp., with 195 illustrations and 32 tables. New York: The Macmillan Company, 1946. \$11.00

Napier's approach to tropical medicine is distinctive. The style is readable and suggests at times the informal clinical lecture. In general, the material is presented systematically, simply and clearly.

The chapters dealing with the diseases of India, which the author knows well, are excellent. This is notably true of the chapter on kala-azar. The importance of malaria has been emphasized, as it should be, by the devotion of many pages to this subject.

Unfortunately, some of the helminthic diseases have been less well handled, and some old errors have been perpetuated. For example, the map showing the distribution of bancroftian filariasis indicates that the disease exists in parts of the Belgian Congo in which *Wuchereria bancrofti* is not indigenous. The names *Trichuris trichiura* and *Trichocephalus trichiura* are used interchangeably to designate the former. Iceland is listed first among the important foci of hydatid disease, whereas the disease is practically nonexistent there today. Its occurrence in England is not mentioned. The sections concerned with various kinds of tapeworms are separated from each other by chapters that deal with quite different kinds of helminthic diseases.

The chapter on climate and disease is interesting. The author's views on house construction and on air conditioning in the tropics are informative.

Some of the more important methods of laboratory diagnosis of tropical diseases are well described.

Many of the illustrations and diagrams are good, but a few might advantageously be improved or even omitted.

ARTHRITIS IN THE MEDITERRANEAN THEATER OF OPERATIONS*

I Incidence of Joint Disease — Clinical Description of Rheumatoid Arthritis

LIEUTENANT COLONEL CHARLES L. SHORT, M.C., A.U.S.

LIKE other organs of the body, the joints are subject to many different forms of disease and injury of both known and unknown etiology. Since this paper deals chiefly with the medical aspects of joint disorders, strictly surgical conditions, such as the immediate effects of trauma and articular infection associated with wounds, have been excluded. Diseases and injuries of the bones, muscles, tendons, bursas and other supporting structures were not studied unless there was subjective or objective evidence pointing toward joint involvement. The conditions variously labeled arthralgia, myositis, myalgia and fibrositis, although not strictly forms of arthritis, were included, since they are often confused with actual joint disease clinically and are usually put under the heading of arthritis in military medical statistics; furthermore, these diagnoses were frequently encountered in the case records in the Theater and bore a high rate of disability. Again, what may be called psychogenic or psychosomatic rheumatism formed an object of study. Although belonging to the neuroses, this condition bears a relation to the handling of joint disease that is even more important under military conditions than in civilian life. Low-back pain was excluded from consideration, unless actually due to arthritis or forming a part of the symptomatology of the arthralgia or psychogenic rheumatism group. Finally, rheumatic fever, although having certain features in common with rheumatoid arthritis and occasionally mistaken for one of the arthritides, was regarded as an independent, generalized disease and was therefore considered only in the differential diagnosis.

Material for this study was gathered from epidemiologic data available at the offices of the Surgeon, Fifth Army, and of the Theater Surgeon, from hospital records, by questionnaires sent to general hospitals, by conferences with medical officers throughout the Theater and by personal observations.

INCIDENCE OF ARTHRITIS

No over-all figures were available to determine the incidence of the arthritic diseases† among American troops in the Theater. Samples, chiefly from hospital admissions, dispositions or patients remaining, however, were utilized to give a rough indication of the extent of the problem. The six evacuation hospitals serving the Fifth Army in August, 1944, are considered first. During one week 2149 soldiers were admitted to these hospitals for disease. Those complaining of nontraumatic musculoskeletal disorders numbered 128, or 3.4 per cent, of the total. The dispositions to duty or to the base for the month of August, 1944, are shown in Table 1. Although the arthritic diseases made up only a small proportion of either the weekly (3.4 per cent) or the monthly (3.1 per cent) dispositions, it is possible that the incidence would have been increased in figures obtained during months of rain and cold.

Table 2 presents the breakdown of medical admissions to a station hospital from August, 1943, through April, 1945. Again, conditions grouped under the heading "arthritis" made up a small proportion of the total—6.5 per cent of the non-infectious cases and 1.8 per cent of the total admissions to the medical service. When the arthritic patients admitted to general hospitals were enumerated, the rate was somewhat higher—1.8 per cent of total admissions and 4.1 per cent of patients entering the medical services (Table 3). Comparable figures were obtained from a study of the cases remaining in hospitals in the Peninsular Base Section on a given day of each month from March through November, 1944. The arthritic cases, including arthritis, myositis and myalgia, in the musculoskeletal group were separated from the remainder, consisting chiefly of low-back pain, pes planus and bone disease (Table 4). A daily average of 343 patients with arthritic diseases were hospitalized in this base section, making up 3.3 per

*The following material represents a condensation and a certain amount of revision of parts of a clinical monograph on arthritis prepared at the direction of the Surgeon, Mediterranean Theater of Operations, United States Army, and submitted to him in final form in June 1945.

†In this section the term "arthritic diseases" includes in both text and tables conditions diagnosed as arthralgia, myalgia, myositis and fibrositis.

A Future for Preventive Medicine By Edward J. Stuehlitz, MS, MD 8°, cloth, 77 pp. Studies of the New York Academy of Medicine Committee on Medicine and the Changing Order. New York: The Commonwealth Fund, 1945. \$1.00.

Dr. Stuehlitz presents the argument that the full achievement of preventive medicine requires the co-operation of the physician, the individual patient and the collective public. He points out that there are still many unexplored fields and urges more research in public health and medicine, particularly with reference to the health problems of middle and old age, better medical education and better public instruction. He believes that the conception of preventive medicine should be broad in scope. He divides his text into three parts: definitions pertaining to preventive medicine, including a classification of preventive activities, health over the last forty years, comprising a statistical study of morbidity and discussion of major present health hazards, and a program for preventive medicine, including its relation to environment, research and education and to the individual. A selected bibliography is appended to the text. This monograph should prove of value to all interested in public health and should be in all medical libraries.

NOTICES

JOSEPH H. PRATT DIAGNOSTIC HOSPITAL

Bennet Street, Boston
Lecture Hall, 9-10 a.m.

MEDICAL CONFERENCE PROGRAM

- Friday, March 7 — Cancer of the Stomach, 1937-1947. Dr. Robert M. Kark.
Wednesday, March 12 — Clinicopathological Conference. Drs. Robert P. McCombs and H. E. MacMahon.
Friday, March 14 — Carcinoma of the Cecum. Dr. Donald T. Chamberlin.
Wednesday, March 19 — Pediatric Clinicopathological Conference. Drs. James M. Baty and H. E. MacMahon.
Friday, March 21 — Radioactive Iodine in Hyperthyroidism. Dr. Earle M. Chapman.
Wednesday, March 26 — The History of the Concept of Functional Nervous Disease. Dr. A. Warren Stearns.
Friday, March 28 — The Effect of Carotid Sinus Stimulation on Anginal Pain, and Other Considerations. Dr. Samuel Levine.

On Tuesday and Thursday mornings, Dr. S. J. Thannhauser will give medical clinics on hospital cases. On Saturday mornings, clinics will be given by Dr. William Dameshek. Medical rounds are conducted each weekday by members of the staff from 12:00 m. to 1:00 p.m. in the Lecture Hall.

All exercises are open to the medical profession.

TUFTS MEDICAL ALUMNI ASSOCIATION

The annual dinner meeting of the Tufts Medical Alumni Association will be held at 6:30 p.m. on Wednesday, March 26, at the Copley-Plaza Hotel, Boston. The guest speaker will be Thomas A. Hendricks, secretary of the Council on Medical Service of the American Medical Association, who will speak on the topic "Public Relations, Economics and the Doctor." President Leonard Carmichael of Tufts College will give a progress report. Dr. A. K. Paine, president of the Alumni Association, will speak on alumni affairs. Dr. John T. Batal, representing the twenty-five-year class, will speak on the subject "Time Marches On." Dr. Lewis B. Hayden, of Livermore Falls, Maine, will represent the fifty-year class. Dr. Dwight O'Hara will speak as dean of the Medical School and as president of the Massachusetts Medical Society. More than six hundred medical alumni are expected to attend this event. Dr. John J. Todd will preside.

AMERICAN COLLEGE OF SURGEONS

The fourth of a series of seven sectional meetings of the American College of Surgeons will be held in Providence on March 28 and 29, with headquarters at the Providence-Biltmore Hotel, Rhode Island and the surrounding states will participate. The medical profession at large, medical students and hospital personnel are invited to join with the fellows of the College in the meeting, which will be addressed by nationally prominent visiting and local speakers.

POSTGRADUATE INSTITUTE

The Eleventh Annual Postgraduate Institute of the Philadelphia County Medical Society will be held on the Rod Garden of the Bellevue-Stratford Hotel in Philadelphia on April 15, 16, 17 and 18. The theme of the meeting will be symposiums on medical progress. Among the subjects to be covered are thyroid disease, diabetes, vitamins and hormones, intestinal disorders, kidney pathology, peripheral vascular diseases, antibiotics, hypertension, diseases of the lung, neuropsychiatry, diseases of the stomach and duodenum, allergy, skin disorders and otolaryngologic diseases. There will also be two evening meetings at the building of the Philadelphia County Medical Society on the subjects of the disorders of childhood and infancy and of obstetric and gynecologic problems. There will be a complete array of technical exhibits, as well as a number of interesting scientific exhibits.

The registration fee for the entire course is \$5.00 for non-members of the society. Out-of-town physicians planning to attend the meeting are urged to make their hotel reservations immediately. Further information may be obtained from Gilson C. Engel, M.D., Director, 301 South 21st Street, Philadelphia 3.

BOSTON CITY HOSPITAL HOUSE OFFICERS' ASSOCIATION

The March 25 lecture of the Tuesday evening lecture series of the House Officers' Association of the Boston City Hospital will be held in the new Cheever Amphitheater, Dowling Building, at 7:00. Dr. Cornelius P. Rhoads, director of the Memorial Hospital, New York City, will speak on the subject "The Metabolic Aspects of Cancer."

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING THURSDAY, MARCH 13

FRIDAY, MARCH 14

- *9:00-10:00 a.m. Carcinoma of the Cecum. Dr. Donald T. Chamberlin. Joseph H. Pratt Diagnostic Hospital.
*10:00 a.m.-12:00 p.m. Medical Staff Rounds. Peter Bent Brigham Hospital.
12:00 m.-1:00 p.m. Clinicopathological Conference (Boston Floating Hospital). Joseph H. Pratt Diagnostic Hospital.

MONDAY, MARCH 17

- *12:15-1:15 p.m. Clinicopathological Conference. Peter Bent Brigham Hospital.

TUESDAY, MARCH 18

- 12:00 m.-1:00 p.m. Dermatological Service, Grand Rounds. Amphitheater, Dowling Building. Boston City Hospital.
*12:15-1:15 p.m. Clinicoradiogenetological Conference. Peter Bent Brigham Hospital.

WEDNESDAY, MARCH 19

- *9:00-10:00 a.m. Pediatric Clinicopathological Conference. Drs. James M. Baty and H. E. MacMahon. Joseph H. Pratt Diagnostic Hospital.
*11:00 a.m.-12:00 p.m. Medical Clinic. Amphitheater, Children's Hospital.
*12:00 m. Clinicopathological Conference (Children's Hospital). Amphitheater, Peter Bent Brigham Hospital.
*2:00-3:00 p.m. Combined Clinic by the Medical, Surgical and Orthopedic Services. Amphitheater, Children's Hospital.

*Open to the medical profession.

(Notices continued on page xvii)

hospital Officers from this hospital made up the Disposition Board for the Fifth Army. A total of 3991 patients with various conditions were reclassified for limited service between February 22, 1944, and May 1, 1945 (Table 7). The importance of arthritis is evident from these data, since these

TABLE 5 *Man-Days Lost through Hospitalization in the Mediterranean Theater*

PERIOD	MAN-DAYS LOST			AVERAGE NO OF ARTHRITIC PATIENTS IN HOSPITAL
	TOTAL	FOR ARTHRITIS	FOR DISEASE	
1943	4 016 000	59 000	2 704 000	244

TOTAL	12 457 000	275 000 (2%)	8 338 000 (67%)	

patients constituted the largest group among those reclassified for disease and were surpassed in the whole number only by neuropsychiatric cases and battle casualties.

During World War I, a total of 65,192 patients suffering from joint disease (exclusive of rheumatic fever) were admitted to Army hospitals.¹ Until the data for World War II are finally compiled, no comparison is possible, but owing to the greater size of the Army alone, it is probable that the total figure will be at least doubled. In 1941 about 35,000 veterans disabled by arthritis were receiving compensation, including, of course, those whose illness had started after discharge from the service. As yet, little has appeared in the literature on the military incidence of joint disease in World War II. The admissions to two British general hospitals in France in 1940 (during a period of combat inactivity) indicated a much higher incidence of arthritic disease in the British Army at that time than in the United States Army in the Mediterranean Theater.² In fact, 10 per cent of all those patients admitted to hospitals and 20 per cent of those entering the medical service referred their symptoms to the joints or other supporting structures (fibrositis). The experience of the Medical Division of a United States Naval Base Hospital operating at Casablanca

*Includes arthritic patients.

The number of patients evacuated from the Theater for arthritis may be estimated from a sample containing the distribution according to diagnoses of evacuees for disease from the Mediterranean Base Section from March 1 to June 1, 1944. (During this period most of the patients going to the Zone of the Interior from the Theater left via this base section.) If neuropsychiatric disorders were excluded, arthritis was outnumbered only by peptic ulcer and outranked such conditions as pulmonary tuberculosis, rheumatic fever with or without valvular heart disease, trench foot, asthma, malaria and nephritis (Table 8). The patients evacuated for disease from the Theater in 1943, 1944 and the first four months of 1945 numbered 31,320. Applying the ratio (5.0 per cent) found in Table 8 to this figure, the number evacuated for arthritis may be calculated at 1566. The true figure is somewhat higher, since the total until December 1, 1944, for this group of diseases from eleven of the fifteen general hospitals in the Theater amounted to 1507.

in 1943 and 1944 has recently been published.³ In the first year of operation, 36 cases (4.8 per cent) among 744 admissions were diagnosed as arthritis.

5) The figure obtained was 275,000 man-days for this period of twenty-eight months.

The importance of arthritis as a cause of manpower loss was more significantly measured by the number of soldiers rendered unavailable for combat owing to reclassification for limited service or removed entirely from the Theater by evacuation than by the morbidity figures given alone. The liability of the arthritic patient to escape returning to full duty was suggested, however, by the slightly increased rate (4.1 per cent) found on the medical services of three general hospitals (Table 3), com-

pared with figures from other types of hospitals and for those in the Peninsular Base Section as a group. Any medical patient, of course, was less likely to return to full duty once in a general hospital but the data considered below demonstrate that a high percentage of those with joint disease failed to resume their previous duty status. Table 6 presents the combined figures for dispositions of patients with arthritis from ten general hospitals

as obtained from written questionnaires and from the records of the Medical Service of the Forty-Fifth General Hospital, with the period covered chosen

to exclude the time when this hospital was receiving many patients from other general hospitals for evacuation. For comparison, the ratios of dispositions of the remainder of the medical patients in this hospital and of all patients hospitalized for disease in the Theater are presented. The inference can be drawn from this table that nearly half the patients with arthritis reaching a general hospital in the Theater were evacuated, another fourth being reclassified for limited service, and that the

incidence of evacuation and reclassification was greater among arthritic patients than among the run of medical patients.

It was not possible to gather extensive data regarding the disposition of arthritic patients from other installations than general hospitals. However, many of the 235 soldiers with joint disease discharged from Fifth Army evacuation hospitals during August, 1944 (Table 1), returned to duty was not available, but an indication was furnished from the records of the Third Convalescent Hos-

genic rheumatism" are included in these figures, and the number of cases in this group, in addition to those in the arthralgia group, nearly equals the sum of the cases of definite arthritis.

Numerical data concerning the relative incidence of the various types of arthritis encountered in the Theater were available only from general hospitals. The impression gained, however, from conferences with medical officers in station and evacuation hospitals was that the patients with arthralgia made up by far the greatest proportion of those with joint symptoms. This opinion is reflected in the relatively large number of such patients in general hospitals, although in other installations many patients were returned to some form of duty and therefore never reached a general hospital. Figures from two British general hospitals in 1940, which were evidently acting chiefly as station hospitals

(unqualified) and about a fourth, muscular rheumatism or myositis.¹ Gonorrheal arthritis comprised about 12 per cent of the cases of arthritis tabulated in World War I, probably exceeding in incidence for reasons discussed below, this form of infectious arthritis in the Mediterranean Theater. Although there are variations in individual hospitals and in groups of hospitals, no significant difference in incidence in the Theater between rheumatoid and hypertrophic arthritis is discernible when the available figures are combined. In the two British general hospitals mentioned above, about twice as many patients with rheumatoid as with hypertrophic arthritis were tabulated² — a ratio confirmed in the United States by Kinsey,⁴ whose study, however, was concerned only with patients separated from the service for disability. Boland and Corr's⁵ results agree more nearly with those obtained in

at that time, are in agreement, several times as many cases being classified as "fibrositis" as those with real arthritis.² In a study by Boland and Corr⁵ of 450 consecutive cases diagnosed as arthritis or an allied organic condition before admission to the Medical Service of Hoff General Hospital, patients with rheumatoid or hypertrophic arthritis were outnumbered by those with psychogenic rheumatism. In this study the diagnosis of fibrositis was made infrequently, perhaps because of the care with which the authors investigated the possibility that emotional factors produced somatic symptoms in the musculoskeletal system. At the Army and Navy General Hospital at Hot Springs, Arkansas, the incidence of the various types of rheumatic disease based on 2000 consecutive admissions in 1944 was as follows: rheumatoid arthritis, 34.3 per cent, psychogenic rheumatism, 18.8 per cent, fibrositis, 13.6 per cent, hypertrophic arthritis, 12.4 per cent, gonorrheal arthritis, 1.4 per cent, and miscellaneous, 19.5 per cent.⁶ The criteria governing the admission of patients to this hospital are not available, but it is significant that cases of fibrositis and psychogenic rheumatism made up about a third of the total number. The figures for World War I show that about half of 65,192 soldiers admitted for joint disease were labeled arthritis

in the Mediterranean Theater, although a slightly greater number of cases of rheumatoid arthritis were found, and nearly three times as many patients with rheumatoid as with hypertrophic arthritis were admitted to the Army and Navy General Hospital.

In conclusion, since exact figures are not available, the relative incidence of the various types of arthritis encountered in the Theater may be summed up briefly. Patients with joint symptoms but without objective changes were encountered more frequently than those with any of the organic types of arthritis. In many of this group, a psychogenic origin of symptoms was demonstrated when sought for. Among those with real arthritis, no significant difference in incidence was demonstrated between the rheumatoid and the hypertrophic types. Cases of specific infectious arthritis were relatively infrequent. The distribution was roughly as follows: arthralgia, 40 per cent, rheumatoid and hypertrophic arthritis, 25 per cent each, and specific infectious arthritis, less than 10 per cent (Table 10). So far as prognosis for return to duty was concerned, patients with arthralgia presented a much more favorable outlook than those in either the rheumatoid or hypertrophic groups.

from the Army on certificates of disability for discharge in the last three months of 1942 at the Station Hospital, Camp Blanding, Florida. Patients with chronic arthritis made up 5 per cent of the total, and were outnumbered only by patients with psychoneurosis, duodenal ulcer and psychoses. In spite of such screening, which was probably

cases, although some have undoubtedly been included under fibrositis or variations of that term. For these reasons no exact information is available regarding the types of arthritis seen in the ten general hospitals, combined figures from which were obtained from answers to the questionnaire, but the large size of the arthralgia-myositis group, which

representative of the training camps in the United States, arthritis constituted, as shown by the data presented in this section, one of the important causes of disability in troops overseas.

TYPES OF ARTHRITIS

The "Index of Standard Diagnoses" generally used in Army hospitals did not, until amended, encourage an attempt at an exact diagnosis of the arthritides of unknown cause. Under Diagnosis

exceeded any of the others, is apparent (Table 9). The disposition of each type is also expressed in this table, although the figures are, of course, not of great significance on account of the groups with type unspecified. As might be expected, they show a trend toward return to duty in the acute and infectious groups and demonstrate clearly the more favorable outcome in the arthralgia group as compared to that in the cases of real arthritis.

Table 10 presents a classification of the patients

0750, the medical officer was not asked to specify whether he was dealing, for example, with rheumatoid or hypertrophic arthritis. In some hospitals, additional diagnoses were provided for this purpose, but in others any such subdivision was left to the initiative of the ward officer. The written questionnaire sent to general hospitals was drawn up with this point in mind, and headings were provided for both acute and chronic arthritis, type unspecified, as well as for rheumatoid and hypertrophic arthritis. Arthralgia, myositis and myalgia were believed to be the most frequent terms used for this group of

with arthritis discharged from the Medical Service of the Twelfth General Hospital. The opportunity was presented of examining the discharge summaries of all the patients enumerated and formulating an opinion concerning the correct diagnosis when the type of arthritis was unspecified or when the diagnosis seemed at variance with the facts available. The breakdown into types of arthritis was therefore revised and was not entirely in accord with the medical records or with the Army nomenclature. Owing to the completeness of the records of this hospital, a group of cases labeled "psycho-

Regarding physical examination, the consensus was that objective joint changes, chiefly swelling, were necessary for a definite diagnosis of rheumatoid arthritis involving the peripheral joints. One obvious exception to this rule occurred when swelling had previously been noted in the clinical record accompanying the patient in the process of evacuation. A careful check of the peripheral joint findings in the series of 132 patients with diagnoses of rheumatoid arthritis showed only 11 without evidence of articular swelling, 3 of whom had definite limitation of motion. The remainder fulfilled the diagnosis by characteristic symptomatology and by multiple and symmetrical joint involvement limited to tenderness and pain on motion. Another medical officer with a large experience in arthritis stated that he had also occasionally made the diagnosis of rheumatoid arthritis under these conditions. The tendency of the disease to be bilateral, often in a strikingly symmetrical fashion, is especially characteristic of rheumatoid arthritis. In this series of 132 cases, 87 per cent of patients with extraspinal involvement had at least one pair of corresponding joints affected. On the other hand, 12 cases were seen with entirely unilateral involvement of more than one joint, the duration in 6 averaging nearly ten years. One interesting finding by Boland,⁷ in a general hospital in the United States, was not confirmed. In 70 per cent of his 41 cases of rheumatoid arthritis, the involvement was confined to the lower extremities. A check of 112 patients with peripheral arthritis in the Mediterranean Theater disclosed that the upper extremities alone were involved in 15, the lower extremities in 22 and both in 75. Similarly, Boland found 41 per cent with metatarsophalangeal and toe involvement in contrast to 10 per cent with arthritis of corresponding joints of the hands, whereas a study of the 112 patients in the Theater revealed an involvement of 30 per cent and 53 per cent respectively.

Weight loss, cold, clammy extremities, tremor, muscle atrophy and weak grips were also detected on physical examination. Intis, which may be a manifestation of rheumatoid arthritis, or a history of this condition, was encountered in only 3 per cent of the series. Fever, with temperatures occasionally ranging as high as 102°F, was recorded in about a sixth of the patients. The incidence of splenomegaly, lymphadenopathy and rheumatoid nodules was much less than that usually observed in civilian practice, the nodules being found in only 5 per cent of patients with peripheral joint involvement. This difference was probably associated with the relative mildness of the disease: an estimate of the total severity in the series at the Sixth General Hospital showed the cases to be mild in 33 per cent, moderate in 60 per cent and severe in only 7 per cent.

Although no specific laboratory test for rheumatoid arthritis is known, the sedimentation rate has been found helpful diagnostically, chiefly in a con-

firmatory sense, and although it is recognized in civilian practice that a patient may have rheumatoid arthritis and a normal sedimentation rate, this group has been small and probably numbers less than 10 per cent. From examination of the case records at the Sixth and Twelfth general hospitals, the reverse was true. The rate was increased in only 52 per cent of 112 patients in the former series, and in 36 per cent of 52 patients on whom the test was performed in the latter. The difference may result from the more advanced type of case seen in civilian hospitals or because more accurate procedures, such as the Rourke-Ernstene method, have been employed than those generally used in Army laboratories (Wintrobe and Westergren). The white-cell count was variable and not of diagnostic importance and few patients in the Theater showed an anemia consequent to the disease. It was generally agreed in the Theater that articular x-ray examination usually proved negative except in cases of rheumatoid spondylitis. In the Twelfth General Hospital only about a sixth of the patients with peripheral joint involvement showed changes (with the exception of soft-tissue swelling), whereas in the Sixth General Hospital 30 per cent evidenced varying degrees of bony atrophy and another 8 per cent, joint narrowing or destruction. The conclusion can thus be drawn that the diagnosis of rheumatoid arthritis in the stage usually encountered in the Theater generally had to be established by the clinical picture rather than by laboratory or x-ray study.

Differential Diagnosis

The majority of observers in the Theater stated that rheumatic fever was readily distinguished from rheumatoid arthritis. Acute types of rheumatoid arthritis, however, as well as rheumatic fever tending toward long-continued joint involvement, at times furnished difficulty. Usually the distinction between the two diseases could be made after several weeks' observation, but in any event, the indications for treatment and disposition were similar, irrespective of the final diagnosis. Hypertrophic arthritis was ordinarily easily differentiated from rheumatoid arthritis. Exceptions occasionally occurred in patients with hypertrophic arthritis showing a marked degree of synovitis and in those, usually in the older age groups, who had rheumatoid arthritis clinically but demonstrated hypertrophic changes on x-ray study. The distinction between rheumatoid arthritis and the conditions grouped under the heading of arthralgia proved especially difficult, even in cases in which the localization was apparently extra-articular. In general, the presence or absence of objective joint changes constituted the deciding factor, since, as mentioned above, the diagnosis of rheumatoid arthritis was rarely made in their absence. The sedimentation rate and x-ray examination were not of great value in this type of case,

RHEUMATOID ARTHRITIS

In this paper no attempt is made to present an inclusive description of rheumatoid arthritis derived from the literature or from observations in civilian practice. Instead, the more important aspects of the disease as seen in the Mediterranean Theater will be outlined, comparison being made, when indicated, with civilian experience. The name "rheumatoid arthritis" is used throughout, both for the sake of uniformity and because it was generally, if not universally, employed in the Theater. Rheumatoid spondylitis, although believed to be a variation of rheumatoid arthritis rather than an independent entity, and atypical forms are chiefly discussed for greater convenience in separate sections.

The age distribution in 132 consecutive cases of rheumatoid arthritis personally studied is presented in Table 11. About 75 per cent of patients were

TABLE 11 Age Distribution of 132 Patients* with Rheumatoid Arthritis Studied in the Sixth General Hospital

AGE GROUP	NO. OF CASES	PERCENTAGE
15-19	0	0.0
20-24	29	22.0
25-29	30	22.8
30-34	39	29.5
35-39	18	13.6
40-44	11	8.3
45-49	5	3.8
50-54	0	0.0

*Mean age 30.8 years

from twenty to thirty-four years of age, and the mean age was thirty years and nine months. Since the age distribution of the troops involved is not known, these figures give no clue regarding a predilection of the disease for any age group. A comparison may be made, however, with the mean age of thirty-four years and nine months in 101 cases of arthralgia and thirty-eight years and ten months in 51 cases with hypertrophic arthritis, both series having been obtained from the records of the Twelfth General Hospital.

That the cause of rheumatoid arthritis is not yet known may be stated without further discussion. Precipitating factors in civilian series have been found to be infections (especially of the upper respiratory tract), trauma, exposure to cold and dampness and emotional stress. Such factors were elicited in a minority of the patients with an onset recent enough to make the history reliable. Nearly half the 132 patients in the series, however, definitely dated the onset of the arthritis or noted an exacerbation in a previously existent disease within two months following their landing in North Africa. These findings are difficult to evaluate but suggest a possible association of the course of the disease with the hardships and anxieties of overseas service

or the unfavorable climatic conditions of the winter of 1942-1943.

Diagnosis and Clinical Features

There is no specific diagnostic test for rheumatoid arthritis, but the disease must be considered an entity, since both the clinical picture and the roentgenologic and pathological findings are unmistakable in advanced cases. Such patients, of course, with the exception of those with spondylitis, rarely escaped the screening process of induction and preliminary training and were only occasionally encountered in the Theater. The diagnosis of the disease under such conditions depended on the demonstration of a fairly characteristic total clinical picture, in addition to the exclusion of other forms of organic or functional joint disease. So far as the history is concerned, an inquiry into the previous existence or past attacks of joint disease is of primary importance. In the series of 132 patients, slightly over half gave a definite history of symptoms consistent with rheumatoid arthritis before induction and about two thirds gave evidence of the disease before arrival in North Africa. The disease had obviously started five to ten years previously in many cases and twenty years or more before admission in 5 patients. A history of previous attacks lasting from a few weeks to several months was usual (although about a third of the patients were in their first attack of less than a year's duration). The majority of patients who had had earlier attacks had never enjoyed a complete remission but continued to have morning stiffness and articular pains of varying severity but evidently insufficient to prevent induction and embarkation. As in civilian practice, the preceding attacks had often been erroneously labeled inflammatory rheumatism or rheumatic fever.

In the diagnosis of rheumatoid arthritis, it is essential to recall that one is dealing with a generalized disease exhibiting well marked constitutional manifestations. A history of easy fatigability, anorexia or weight loss was obtained in 87 per cent of cases in the Sixth General Hospital series, sometimes before the actual onset of arthritis. These symptoms, one or more of which could, of course, have been elicited from a large proportion of the soldiers in the Theater, were of less diagnostic value than in civilian practice, unless of a severe degree. Vasomotor instability, evidenced by cold extremities, often with increased sweating, was found in about two thirds of the patients in the series, and an equal number had numbness of the hands or feet, with paresthesias variously described as tingling, burning or stinging. Motor weakness, especially of the grips, and tremor were additional neurologic symptoms. Since many patients with rheumatoid arthritis had minimal articular signs, the presence of the symptoms listed above was of real diagnostic assistance.

rheumatoid arthritis. The diagnosis is established by the ruling out of specific infectious arthritis or gouty arthritis and by the later development of unmistakable rheumatoid arthritis.

This form was generally recognized in the Theater and comprised 18 per cent of cases with peripheral joint involvement in the series. The diagnosis was made under a varying terminology in addition to rheumatoid arthritis, but usually as "arthritis, infectious, cause undetermined." Proper emphasis was laid on the importance of eliminating a specific infectious arthritis by means of culture of the synovial fluid and examinations for genitourinary gonorrhea. A therapeutic test with chemotherapy was also a frequent procedure — in fact routine in some hospitals — but usually without definite effect on the course of the arthritis. Nevertheless, this condition tended to subside gradually, irrespective of treatment, and often went into a complete remission. If a remission took place, it seemed reasonable to discharge the patient to limited service or to duty in the Zone of Communications.

RHEUMATOID SPONDYLITIS

Since this variety of rheumatoid arthritis affects males about ten times as often as females and since its onset is most frequent in the second and third decades of life, a relatively large number of cases was expected in soldiers. This expectation has been fulfilled, according to available reports in the literature, the spinal type even outnumbering the peripheral type of rheumatoid arthritis in a British Army series and comprising 37 per cent of 89 patients with rheumatoid arthritis in a general hospital in the United States.⁵ In the Mediterranean Theater the incidence was not so high, averaging 20 per cent of patients with rheumatoid arthritis at the Sixth General Hospital but lower in the records of other hospitals, where the condition was not especially looked for and was not always recognized when present. The diagnosis of rheumatoid spondylitis was made clinically with certitude in advanced cases with nearly rigid spines and later confirmed by the characteristic x-ray appearance of the sacroiliac joints. In earlier cases, it was confused at first with various types of organic and functional low-back conditions, and the diagnosis again was made by the bilateral, destructive changes seen in roentgenograms of the sacroiliac joints. A few cases were noted with the clinical picture of rheumatoid spondylitis, including marked constitutional symptoms, but with repeatedly negative x-ray examinations. In these patients, a presumptive diagnosis of rheumatoid spondylitis was made, without the opportunity of confirmation, since the symptoms were severe enough to warrant evacuation.

On account of the frequency of rheumatoid spondylitis in soldiers, x-ray examination of the lower back with careful interpretation of the sacroiliac joints seemed indicated in every patient with

persistent back symptoms. In two small series examined in the Theater, 5 per cent and 10 per cent of patients, respectively, were found to have this condition, whereas in 181 cases with back complaints studied in a general hospital in the United States, 33, or 18.7 per cent, warranted a diagnosis of rheumatoid spondylitis.⁶ The extent of the x-ray findings often seemed out of all proportion to the duration of the symptoms and the degree of disability. Not a few soldiers with advanced changes on x-ray examination fought through a campaign, including a parachutist who had made a number of jumps.

SUMMARY

The general incidence of arthritis among American troops hospitalized for disease in the Mediterranean Theater was estimated to be relatively low (about 3 per cent), but approximately 275,000 man-days were lost for this reason from January, 1943, through April, 1945. As a source of permanent loss of man power from the Theater by evacuation or from combat troops by reclassification, arthritis was highly important.

Patients without objective evidence of joint disease nearly equaled in incidence those with evident arthritis. In general hospitals, the distribution was estimated as 40 per cent for arthralgia and psychogenic rheumatism, 25 per cent each for rheumatoid and hypertrophic arthritis and less than 10 per cent for specific infectious arthritis.

The onset of rheumatoid arthritis or an exacerbation was frequently noted following arrival overseas. A history of arthritis prior to induction was given in about half the cases, and before embarkation in about two thirds. Helpful points in diagnosis were a history of constitutional, vasomotor and neurologic symptoms and a finding of symmetrical joint involvement. The diagnosis of rheumatoid spondylitis was made in about a fifth of the patients with rheumatoid arthritis. Laboratory tests, including the sedimentation rate, and x-ray films were not of primary diagnostic value. The total severity of the disease was generally less than that noted in civilian hospitals. Difficulty was experienced in the differential diagnosis of arthralgia and psychogenic rheumatism. An attempt at treatment was made only in milder cases considered susceptible to remission. Only 20 per cent of patients with rheumatoid arthritis were returned to duty.

except as a check on the clinical impression. Daily questioning of the patient, with careful examination of painful joints over a period of several weeks, often clarified the decision. When doubt finally existed and the patient's course remained stationary, the tendency was to abandon the diagnosis of rheumatoid arthritis for the time being and to return the soldier to some form of duty. In any patient with articular complaints without objective findings, the possibility of so-called "psychogenic rheumatism" was of course strongly suspected, and an attempt made to establish the presence of an underlying neurosis. Further details will be presented in a subsequent paper. Cases of traumatic arthritis were usually readily separated from those of rheumatoid arthritis except in the knee, where the physical finding of a dislocated meniscus or other injury was occasionally simulated by rheumatoid arthritis involving the joint. In such cases diagnostic joint aspirations and examination of the synovial fluid were apparently not utilized often enough. In certain patients in whom the joints of the feet were involved by rheumatoid arthritis, a diagnosis of foot strain was erroneously made at first.

Treatment

No specific treatment for rheumatoid arthritis has as yet been found, and none of those claimed to be specific without convincing evidence were tried in the Theater, including parenteral injection of gold compounds, massive doses of vitamin D and the use of autogenous or stock vaccines. A few patients were given fever therapy, usually with intravenous typhoid vaccine, without lasting beneficial results. Opinion was divided regarding the removal of focal infection. In a few hospitals, a rather thorough check for foci of infection was made. The results of removal or treatment of supposed foci were disappointing on the whole, although successes were reported in a few cases. In most patients, only obvious foci were removed—for example, the tonsils when the onset of the arthritis followed an acute tonsillitis or certain teeth when marked dental sepsis was present. Again, success in influencing the course of the disease was seldom attained. In well marked cases or those of long standing, the tendency was to evacuate the patient without an attempt at more than palliative treatment. In milder cases, especially those with early, acute involvement of one or a few joints, hospitalization was maintained until the patient could be returned to some form of duty or the chances of a remission seemed remote. Such patients were given general treatment, including bed rest, relief of pain and physical therapy, and were usually examined for focal infection.

Disposition

A compilation from ten general hospitals, with the elimination of those receiving many patients

from other general hospitals for evacuation, revealed that about a fifth of the patients with the diagnosis of rheumatoid arthritis returned to full duty, the large majority of the remainder being evacuated to the Zone of the Interior (Table 9). The policies that governed this distribution may be summarized as follows. It was generally agreed that only an occasional patient merited a return to full duty, including those in their first acute attack with apparent complete subsidence and those of mild severity with duties that lent themselves to favorable living conditions, opportunities for rest and a chance for medical supervision. Some of the records examined, however, indicated that these conditions were not entirely fulfilled, and that further hospitalization would be necessary. Essentially the same conditions were laid down for limited service, except that a few hospitals determined this disposition more on the patient's ability to perform some kind of duty at the time of discharge than on the probability of his being able to continue a particular task. That more advanced cases and milder cases with repeated hospitalization should be evacuated was universally recognized—a fact that accounts for the high proportion of such dispositions.

Owing to the variability of the course of rheumatoid arthritis, it seems impossible to lay down rules for disposition that would finally prove applicable to every case encountered in overseas service. When the diagnosis is still in doubt, the soldier should certainly be returned to whatever duty he can perform at the time. But since the disease bears a definite threat of chronicity and long-standing disability, evacuation to the Zone of the Interior should provide the best chance for a relatively favorable outcome once the diagnosis has been established. Certainly, the hardships and anxieties of overseas service are likely to have a deleterious effect on the progress of the disease. Furthermore, it is not to the best interests of the service to return a man to duty who bears the liability or even probability of recurrence. From these considerations, although no figures for such recurrences are available, it is believed that, as with peptic ulcer and active pulmonary tuberculosis, evacuation is indicated in all but a few selected cases.

ATYPICAL RHEUMATOID ARTHRITIS

Although rarer than the usual form of rheumatoid arthritis, an atypical form has been clearly defined in civilian practice. This variety appears acutely and at times follows a definite infection, usually of the upper respiratory tract. It is characterized by severe inflammation of one or a few joints in an asymmetrical fashion and may be accompanied by fever. Foci of infection of presumed etiologic significance are sometimes found, but any direct beneficial result from their removal is open to question, since remissions are more frequent and complete in this type than in the usual varieties of

patients were between the ages of fifty-one and sixty years, 14 were in the seventh and 11 in the fifth decades. Thirty-three of the 52 patients were men, and 19 were women.

The surgical procedures are presented in Table 1. Extensive operations were performed on the stomach in 5 cases and on the large bowel—including a Miles or Mikulicz resection, colectomy and colostomy—in 19. Eight patients had pelvic operations, and if these are combined with the 19 cases in which surgery of the colon was performed, a group of 27 cases is formed, confirming the well known fact that thrombosis and embolism are likely to follow

TABLE 1 *Surgical Procedures Employed*

OPERATION	No. of Cases

operations in the pelvis. Cranial operations in 3 cases and splanchicectomy in 1 case were followed by fatal pulmonary embolism.

It has long been recognized that a history of previous vein trouble may predispose to venous thrombosis. Of 11 patients (22 per cent), 8 had varicose veins, and 3 a history of phlebitis. In 9 (17 per cent), no mention was made in the history of any previous vein trouble. This is a point in examination that should be most diligently sought for, as emphasized below.

The occurrence of postoperative pulmonary embolism according to the time elapsed after operation is summarized in Table 2. The period of greatest liability to the first pulmonary embolism was the sixth to the sixteenth postoperative day, 25 patients falling in this group. The first pulmonary embolus occurred before the sixth postoperative day in 11 cases and after the sixteenth day in 12.

The signs and symptoms associated with pulmonary embolism in the 52 cases are recorded in Table 3. Sagall, Bornstein and Wolff⁵ pointed out

that the clinical course of pulmonary embolism is punctuated by a series of events in which numerous signs or symptoms may be present. In the intervals there may be a complete absence of signs or complaints. It is further stated that on clinico-

FIGURE 1 *Incidence of Death due to Pulmonary Embolism according to Age*

pathological grounds each episode does not necessarily connote a separate pulmonary embolism. One embolus may be associated with several clinical episodes, and conversely, more pulmonary infarcts may be found at autopsy than can be accounted for clinically. The table demonstrates the frequency of elevated temperature, circulatory collapse, dyspnea, tachycardia, cyanosis and chest pain in thromboembolic disease. Chest pain, cyanosis and circulatory collapse have long been considered the earmarks of pulmonary embolism but they are only the most dramatic—not the most frequent—signs. Elevated temperature and tachycardia preceding the onset of dramatic symptoms are far more important warning signs.

The 52 cases were divided into three categories according to the time of death after the first symptoms of pulmonary embolism had been noticed.

TABLE 2 *Occurrence of Pulmonary Embolism according to Postoperative Day*

POSTOPERATIVE DAY	No. of Cases
1	1
2-5	10
6-10	15

26-37	3

This was done to determine if warning signs or symptoms were present, affording the clinician time to adopt preventive measures. Group 1 includes the sudden deaths or patients who died within an hour of the onset of pulmonary embolism, 22 cases (42 per cent) comprise this category. Group 2 was composed of patients who died within two to twenty-four hours after the first known pulmonary

THE PREVENTION OF POSTOPERATIVE PULMONARY EMBOLISM*

An Analysis of Fifty-Two Fatal Cases in Six Years

JAMES A. EVANS, M.D.,† AND RAYMOND J. BOLLER, M.D.‡

BOSTON

INTEREST in venous thrombosis and pulmonary embolism has received great impetus in the past eight years by the simultaneous development of two methods of treatment — namely, venous section and ligation and anticoagulant therapy by heparin or dicumarol or by a combination of these anticoagulants. Unfortunately, in many minds the two methods have become competitive, whereas they should be complementary. There are definite indications for both procedures. It is readily conceivable that in many hospitals where adequate laboratory and clinical experience in the use of dicumarol is lacking, a precise and absolute control of the situation by femoral ligation is the method of choice. With more and more confidence, however, afforded by experience with anticoagulant therapy and statistical support from other workers in this field, in addition to our own, femoral ligations at the Lahey Clinic are, with few exceptions, limited to patients with venous thrombosis who must soon have a second-stage operation, to those with conditions such as hemorrhagic colitis in which an anticoagulant effect would be dangerous, to those with poor liver function and to those with ambulatory recurrence of phlebothrombosis with pulmonary embolism. If there is any hint of venous thrombosis, the present method of anticoagulant therapy is to start immediately with both heparin in Pitkin's menstruum and dicumarol. A single dose of heparin in Pitkin's menstruum prolongs the coagulation time before two hours have passed and protects the patient until a two-day latent period of dicumarol action has elapsed, by which time the prothrombin content has usually dropped. In the rare patient who is resistant to dicumarol the injections of heparin are continued every second day.

In the four years between January 1, 1942, and January 1, 1946, anticoagulant therapy was administered to 127 patients with postoperative venous thrombosis, with or without benign pulmonary embolism, with death in only 2. One patient had bilateral femoral vein ligation and only one dose of dicumarol. The other received inadequate doses of dicumarol and never obtained a prothrombin level within the therapeutic range, he was also given a transfusion, which destroyed the slight effect of the dicumarol, and died of a second pulmonary embolism a few hours later. After January 1, 1946, another

fatal case occurred in a patient with postoperative phlebothrombosis treated by anticoagulant therapy. He had been extremely ill with peritonitis but later had a septic infarct in spite of adequate prothrombin reduction. This infarct ruptured and caused terminal pneumothorax and empyema.

Such a record, together with the experience of Barker¹ with dicumarol and of Loewe, Rosenblatt and Hirsch² with heparin in Pitkin's menstruum, compares favorably with reports of the prevention of pulmonary embolism by venous ligation and section.^{3,4}

These results represent a great advance in the prevention of pulmonary embolism once a warning venous accident has occurred in the form of venous thrombosis or a benign pulmonary embolism. In spite of this advance, death may occur from sudden or unrecognized pulmonary embolism — a situation that must be met by prophylaxis, which is still an important factor in any consideration of postoperative pulmonary infarct. We have therefore attempted to analyze 52 sudden, unrecognized or untreated fatal cases of pulmonary embolism in an effort to ascertain ways and means to reduce the mortality further. These deaths occurred from 1940 to 1946. Forty-eight of the fatal cases were postoperative among approximately 45,000 major surgical operations. In only 2 cases had thrombosis and embolism been recognized and the patient treated after a warning pulmonary embolism, as described above. Two deaths occurred in medical cardiac cases, and 1 patient died before contemplated surgery. Autopsy was performed in 21 cases. The remaining 31 patients gave ample clinical evidence of pulmonary embolism.

That prophylactic exercises are an important factor in the prevention of pulmonary embolism is suggested by a comparison of the number of deaths from pulmonary embolism in a year in two hospitals, in one of which bicycle exercises were faithfully supervised by the nursing staff, and in the other of which these measures had not yet been generally enforced, in the latter there were three times as many deaths from pulmonary embolism as in the former. Because of these figures, we now advocate wiggling of the feet a thousand times a day as being universally and immediately applicable to all types of surgical patients.

Figure 1 illustrates the incidence of death from pulmonary emboli according to age. The greatest incidence occurred in the sixth decade. Seventeen

pected mass in the right lung. In the four days between the time he was first seen and his entry into the hospital, a mild superficial bilateral thrombophlebitis had developed, for which ace bandages were applied. Two weeks later a right pneumonectomy was performed. On the seventh day after operation a low-grade fever developed, and on the eighth day the patient complained of soreness in the thighs along the course of both saphenous veins, the latter subsided in three days, but a mild non-productive cough developed. On the sixteenth postoperative day, after being up for two days, he was suddenly stricken with dyspnea and cyanosis. Roentgenologic examination confirmed a clinical diagnosis of pulmonary infarct. While arrangements for a bilateral femoral ligation were being

†Electrocardiogram positive for cor pulmonale

made, he suddenly became cyanotic, gasped for breath and died. Post-mortem examination revealed pulmonary embolism as the direct cause of death.

Group 3 included 10 cases (Table 6). The actual interval between the benign and the fatal embolism was one to twenty-four days. It is in this group that the most time naturally occurred for the institution of active therapeutic measures if warning signs and symptoms had been properly heeded. Two of the 10 patients gave a previous history of vein trouble, one having had varicose veins, and the other a superficial phlebitis. A third patient was not treated because of a hopeless carcinoma. A fourth patient was treated inadequately by anticoagulant therapy (the second patient treated in the entire group of 52 cases).

This patient was a sixty-two-year-old man who was admitted to the hospital in 1943 for a contemplated nephrectomy for carcinoma of the kidney. On admission, he gave evidence of a bilateral phlebothrombosis and benign pulmonary embolism. Bilateral femoral ligation was performed, and only

one dose (200 mg.) of dicumarol was given. Later that day there was hemorrhage from the right femoral ligation. The vein was retied, and the anticoagulant therapy discontinued. The prothrombin time never dropped to a bleeding level, much less to the therapeutic anticoagulant level. Pulmonary

sepsis developed, and the patient died two weeks later of a second pulmonary embolism. Autopsy showed old and recent pulmonary emboli and thrombi in the iliac veins but none in the inferior vena cava. Later experiences indicate that this patient might have been saved by either ligation of the inferior vena cava or energetic anticoagulant therapy.

Another patient in Group 3 whose history points a moral was a fifty-nine-year-old woman on whom a cholecystectomy was performed in 1940. On the thirteenth postoperative day she complained of pain in the left lower chest that was aggravated by breathing, a diagnosis of pulmonary infarction was made. The temperature rose to 100°F on the day before the infarction occurred and continued at that level until the eighteenth postoperative day, when the patient suddenly died while being given a bed bath. There was no note in the record of any leg examination postoperatively. In 1940 the treatment of choice would have been femoral-vein ligation.

FIGURE 2 *Incidence of Death due to Pulmonary Embolism according to Year*

tion if the legs had shown any evidence of thrombosis. At present, the legs would be routinely examined in the presence of postoperative fever, and anticoagulant therapy begun.

Routine postoperative examination of the legs for evidence of phlebothrombosis should be carried out after all major surgical operations. This should

incident (20 cases, or 38 per cent) Group 3 consisted of patients who died over twenty-four hours after the first signs of thrombosis and embolism (10 cases, or 19 per cent)

From the point of view of treatment, it might be assumed that the patients in Group 1 could not have been saved once the pulmonary embolism had

Convulsions	1

occurred. A careful analysis of the record, however, disclosed the interesting facts presented in Table 4. In 16 of the 22 patients there was ample warning before death to permit adequate prophylaxis, in the form of venous ligation or anticoagulant treatment. Fever or tachycardia, or both, had been present in

15 of these cases for an average of seven days before death. The last patient had fever, tachycardia and mental confusion for three days prior to the fatal pulmonary embolism. Of 5 patients in this category who had a history of varicose veins, 3 died without any warning in the hospital. This leaves only 3 of the 22 cases in which there were no warning signs or history of previous vein trouble.

Of the 20 patients in Group 2, warning signs of thrombotic processes were present in 18 (Table 5). Fever alone or in combination with one or more other signs occurred in these patients from four to seventeen days before the onset of the first known pulmonary episode. In addition, 2 patients gave a

history of previous superficial phlebitis, and 2 had varicose veins. Only 2 in this group of 20 patients gave no premonitory signs or history of previous vein trouble.

It is instructive to review briefly the course of 2 patients in Group 2. One patient, a forty-seven-year-old woman, underwent an anterior gastroenterostomy, enteroenterostomy and cholecystectomy. On the fourteenth postoperative day superficial thrombophlebitis of the right leg developed. On the twenty-second postoperative day a deep venous thrombosis was detected in the left leg. She was then belatedly given dicumarol on successive days in doses of 200, 200, 100, 0, 100, 100, 0, 0, 0, 100 and 100 mg. She was allowed to dangle her feet out of bed on the twelfth day of anticoagulant therapy. Furthermore, a transfusion, which neutralized what anticoagulant effect might have been present, was administered for supportive

reasons that evening. The patient spent a confused night and died suddenly on the following morning. The prothrombin times during the course of treatment were 72, 100, more than 100, 105, 69, 85, 63, 105 and 100 per cent of normal. Since the patient had a so-called "therapeutic level" (below 65 per cent of normal) on only one day, the dosage schedule was obviously inadequate. Moreover, on the day the transfusion was given, the prothrombin time was 100 per cent of normal. The occurrence in rapid succession of thrombotic processes in both legs that occurred in this case supports the present practice of doing bilateral vein ligations even when the veins of only one extremity are clinically involved. Furthermore, the failure of dicumarol in rare cases to produce an adequate fall of the prothrombin percentage is a definite indication for venous ligation or persistence in the administration of heparin in Pitkin's menstruum.

The other case that stands out in this group from the viewpoint of prevention is that of a forty-two-year-old man who entered the hospital for a

cent of the deaths occurred after extensive pelvic or lower abdominal surgery, or both. This poses the question of routine prophylactic administration of heparin in Pitkin's menstruum and dicumarol shortly after such major surgical procedures.

The variability of the signs and symptoms associated with pulmonary embolism emphasizes the fact that a thrombotic process should be suspected postoperatively in every case of fever or tachycardia, or both.

Fifty-two per cent of the initial pulmonary emboli occurred between the sixth and sixteenth postoperative days, although a sufficient number occurred before and after that period to make one continuously on the alert for trouble.

Routine, careful examination of the legs postoperatively is required for evidence of phlebotrombosis.

Complete co-operation between the surgeon and the internist is essential to adequate therapy,

whether it consists of anticoagulants or surgical ligation of the veins.

In 85 per cent of the 52 fatal cases, some preventive measure was indicated by premonitory signs, usually in the form of elevated temperature or tachycardia, or both, occurring a sufficient time before the fatal embolism to allow adequate therapy to be administered.

NEUROPATHIC FOOT LESIONS IN DIABETES MELLITUS*

C. CABELL BAILEY, M.D.,† AND HOWARD F. ROOT, M.D.‡

BOSTON

JOINT changes associated with diseases of the central nervous system were first described by Charcot. At first these changes were considered peculiar to tabes dorsalis and syringomyelia, but with extensive use of x-ray examination, similar changes have been found in other conditions. Leprosy may produce a similar picture, as may injury to a peripheral nerve, as described by Weinberg¹ in soldiers injured in World War I. Bone lesions similar to those in Charcot's joints have also been reported in association with diabetes mellitus.²⁻⁷

This report deals with neuropathic foot lesions that occur in patients with diabetes mellitus and are attributed to the effect of the diabetes on the nervous system. Seventeen cases of neuropathic foot lesions have been detected among approximately 20,000 consecutive cases of diabetes—an incidence of 1/1100. Additional cases have probably escaped recognition.

The earliest gross change detected in the foot with a diabetic neuropathic lesion is a unilateral or bilateral thickening of the tarsal region. No fluid is present in the joint. The swelling is painless, and no redness of the skin, heat or other signs of inflammation are present. These changes progress slowly and usually result in a thickened, deformed foot

with a tendency to eversion and external rotation and a flattening of the longitudinal arch.

On roentgenologic examination the neuropathic foot is similar to the chronic Charcot joint of syphilis except that the destruction is chiefly limited to the

FIGURE 1 Case 5

This x-ray film of the right foot shows destruction of the forward end of the astragalus and of most of the other tarsal bones with soft-tissue swelling.

tarsal and proximal ends of the metatarsal bones. The phalanges may also atrophy and become spindle shaped (Fig. 1). The characteristic appearance is a fragmentation and destruction of the metatarsal and the tarsal bones. The joint spaces disappear as

consist of careful questioning of the patient for pain in the legs, especially in the calf muscles. Even when a negative reply is given, the calf should be tested for tenderness, and an attempt made to elicit Homans's sign. Whether or not the legs were examined postoperatively in 48 surgical cases, and if so, the findings are listed in Table 7. The case records contained no mention of postoperative examination of the legs in 25 patients. Of the 23 patients who were examined, the evidence of peripheral-vein thrombosis was positive in 5 and

the 4 fatal cases in 1945, only 1 of which can strictly be classified as nonpreventable. This case was that of a seventy-six-year-old woman in whom a supra-orbital neurectomy had been performed for right supraorbital neuralgia. Eight hours later she became cyanotic, the respirations were irregular, and she died within an hour. There was no warning of this embolism.

The first of the other 3 fatal cases in 1945 occurred in the patient described above as the second patient in Group 2. He had had repeated venous thromboses

negative in 18. It is probable that in some of the 25 cases in which no mention of examination of the legs was made, signs of phlebothrombosis of the leg veins might have been demonstrated.

A composite picture of the entire series of 52 fatal cases is presented in Table 8. In these cases no measure to prevent pulmonary embolism was deemed justifiable in 1 patient with inoperable carcinoma. The most noteworthy and indeed surprising fact demonstrated, however, is that 44 of 52 patients gave warning of thrombotic processes. This means that in 85 per cent of the cases death from pulmonary embolism might have been prevented if the warning signs had been appreciated and prophylactic measures undertaken. Even 73 per cent of those patients who died of pulmonary embolism within an hour had given some warning signs, such as fever and tachycardia, several days before the fatal embolism. Since early 1942 anticoagulant therapy has been the treatment of choice at the Clinic for phlebothrombosis, with or without benign pulmonary embolism, and for thrombophlebitis, because of this there has developed a stimulus to be wary of thrombotic emergencies, and it is gratifying to note the drop in mortality that has occurred. In Figure 2 the mortality per year is tabulated in the 52 cases studied from 1940 to 1946. Little change is apparent in the first two years (1942 and 1943). The small number of deaths in 1944 and 1945 reflect the clinician's trend to become more conscious of thrombosis and embolism. It may now be possible to achieve a deathless year in cases of pulmonary embolism. That this objective may be closely approached seems possible on a review of

in the leg and a benign pulmonary embolism before femoral ligation was decided on. While being prepared for the procedure he died.

The third death in 1945 occurred in a fifty-two-year-old man in whom a Miles resection had been performed for carcinoma of the rectum. On the morning of the second postoperative day he became disoriented, and ten hours later lapsed into coma with convulsions and dilatation of the right pupil. Pulmonary embolism was entirely unsuspected, and no antithrombotic measures had been undertaken. Autopsy revealed a large embolism in the main pulmonary arteries and tiny thrombotic fragments in the pelvic veins, probably attributable to the operative site.

The fourth fatal case in 1945 was that of a fifty-three-year-old man on whom a Miles abdomino-perineal resection had been performed for carcinoma of the rectum. Wound evisceration occurred on the fourth postoperative day. The day after repair he went into shock and became cyanotic and dyspneic. He was treated for shock, peritonitis and atelectasis (by bronchoscopy). Two days later he died. No mention was made of examination of the legs postoperatively. The diagnosis of pulmonary embolism was apparently not entertained. Autopsy revealed atelectasis and peritonitis, but the direct cause of death was pulmonary embolism, thrombosis of the left common iliac vein was also observed.

SUMMARY

In a review of 52 fatal cases of postoperative pulmonary embolism the greatest number occurred in patients fifty to sixty years of age. Fifty-four per

ge was fifty-six years at the time the foot lesion was discovered The youngest patient was thirty and he oldest sixty-nine years of age The diabetes had

serologic findings were negative There was no clinical evidence of syphilis in any case. Evidence of neuritis was found in 14 of the 17

ipping at the bone margins, characteristic of hypertrophic arthritis, are not seen.

Dr. Shields Warren examined histologically the foot lesions in Cases 1 and 6. In the latter a thigh amputation was necessary because of secondary infection. There was a complete loss of bone structure, numerous spicules of bone scattered throughout the area of involvement undergoing various stages of absorption and the remaining periosteum attempting to form new bone. These changes were partly obscured by the secondary infection. Thus, the lesion was like that in a Charcot joint, being both

tion with an increase in the number of osteoblasts. There were foci of mild degenerative changes of the synovial structure, with numerous areas of round-cell infiltration. Increased vascularity was observed in the pericapsular tissue, the walls of the larger vessels showing some thickening. Examination of several sections of the peripheral nerves revealed no definite abnormality.

CLINICAL AND LABORATORY DATA

Table 1 presents the pertinent data in these cases. In this series of 6 men and 11 women the average

In Key's series of 61 White and 9 Negro patients with Charcot joints, there were no cases in which the diagnosis of neurosyphilis could not be made from the physical and laboratory examinations. In approximately a third of the cases there were no premonitory symptoms, but in the remainder, various symptoms were present, including shooting pain, ataxia, bladder dysfunction, visceral crises, optical atrophy, disturbances of sensation in the lower extremities, Argyll-Robertson pupil, loss of deep reflexes in the lower extremities and a positive Romberg test. In 60 cases the blood Wassermann test was positive in 19 and negative in 41. In 30 cases the spinal-fluid Wassermann test was positive in 11 and negative in 19. Roentgenograms showed excess fluid in the joints and tissues, erosion of the weight-bearing surfaces, the production of new bone, pathologic fractures, loose bodies in the joints and, most important of all, diffuse sclerosis.

The most striking differences between the true Charcot joint and diabetic neuropathic feet are the acute onset of fluid in the joint and the swelling of the extremity that may occur in the Charcot joint, the presence of pain in the Charcot joint during the acute stage, the frequent occurrence of new bone formation in the Charcot joint and the rarity of bone formation in diabetic neuropathic feet, the syphilitic sclerosis of the bone in areas near the involved joint, the almost constant occurrence of other symptoms, signs and laboratory evidence of syphilis in patients with Charcot joints, and the relative infrequency of Charcot joints in the feet.

In this group of cases of diabetic neuropathic feet, there was no clinical evidence of syphilis, and the 2 patients with positive blood Wassermann reactions had negative spinal-fluid findings.

The possibility of ischemic changes secondary to arteriosclerosis was considered, but in 14 of the 17 cases the pulsations in the dorsalis pedis arteries were easily felt and there was no evidence of im-

paired circulation. In the remaining cases, the collateral circulation was poor in 1 and good in 2. These findings, as well as the rarity of the condition as compared with the marked frequency of extreme peripheral arteriosclerosis in diabetes of long duration, make the possibility that ischemic changes play an etiologic role extremely remote.

The findings of other evidences of diabetic neuropathy in 14 of the 17 cases, the fact that other nerve lesions produce similar bone changes and the trophic nature of the lesion all suggest that the arthropathy is a manifestation of diabetic neuropathy.

PROGNOSIS

None of the 17 cases showed any tendency to improve, and in most destruction gradually progressed. No treatment proved efficacious, but orthopedic appliances were used in an effort to relieve weight bearing and to avoid further deformity.

SUMMARY

Seventeen cases of neuropathic foot lesions are reported. All had destruction of the tarsal or metatarsal bones that was roentgenologically similar to that observed in Charcot joints.

Evidence is presented that this bone lesion is trophic in origin and is a manifestation of diabetic neuropathy.

had diabetic nocturnal diarrhea, which is considered a manifestation of diabetic neuropathy

The eyes revealed diabetic retinitis in 9 of 15 cases, in 4 of which retinitis proliferans was distinguished by the ophthalmologist. The following is a typical case report

CASE 6 W W (Case 10917) developed diabetes in 1931, when he was 48 years old. He was first seen in March, 1932, with a history of ascites on and off for 5 years. Peritoneal catheter drainage had been instituted at another hospital. The tube was removed, and closure of the abdominal wound followed in 3 months without subsequent recurrence, no acid-fast bacilli were demonstrated. The patient was given 5 units of regular insulin daily and a diet containing 155 gm of carbohydrate, 71 gm of protein and 97 gm of fat (1777 calories)

He was not seen again until March, 1936, when the blood sugar was 520 mg per 100 cc, and he confessed that he had been careless with his diet. He had developed moderately severe neuritis in the legs and back, with absence of knee and ankle reflexes. The blood pressure was 140/80. The pulsations in the dorsalis pedis arteries were normal. There was no demonstrable leg weakness. The pains and paresthesias in the legs and feet, which were much worse at night, gradually subsided after treatment of the diabetes for several months and with supplementary vitamins. Routine x-ray examination of the left foot disclosed a fragmentation and dissolution of continuity of the tarsal and proximal ends of the metatarsal bones. The foot was thickened grossly, and there was flattening of the longitudinal arch. A diagnosis of neurotrophic foot was made.

In November, 1937, osteomyelitis of the left ankle and a spreading infection required a guillotine amputation followed in 1 month by a left thigh amputation from which the patient made an uneventful recovery. Histologic examination revealed a loss of bone structure and of continuity of the tarsal bones, spicules of bones undergoing absorption and the remaining periosteum attempting to lay down new bone. The joint spaces were lost.

On this hospital admission intermittent nocturnal diarrhea, often with nocturnal fecal incontinence, was first noticed. Examination of the urine revealed a slight trace of albumin, and the blood sugar was 450 mg per 100 cc on admission. The serum protein was 6.6 gm per 100 cc, with a reversal of the albumin-globulin ratio (0.74). The blood pressure was 150/90.

A year later the patient was again hospitalized with an infected callus on the right foot. A fluctuating blood pressure reached 192/110. There was a loss of vibratory sense in the lower half of the right leg and foot and a loss of sensation for hot or cold. The spinal-fluid Wassermann reaction, colloidal gold test and cell count were normal. On repeated examination 10 days later the total protein was 112 mg per 100 cc. He was discharged on December 18, the foot having healed. The nocturnal diarrhea persisted intermittently.

In March, 1939, the patient was readmitted with infection of the bone of the 4th and 5th right toes that required incision and drainage. At that time the neuritis had become much worse and the nocturnal diarrhea had persisted. He stated that the diabetes had been under poor control while 20 units of protamine zinc insulin were being taken. Knee and ankle reflexes remained absent. The infection responded after incision and drainage of the foot, which was done without anesthesia since he had loss of pain sensation in the foot—a so-called "anesthetic foot." He made a gradual recovery.

In January, 1941, the patient was readmitted to the hospital having received a burn on the side of the foot from a heater—the anesthesia had prevented his realizing the excessive heat. He recovered with conservative treatment. Examination of the urine revealed a quantitative albumin of 0.8 gm per 100 cc. On admission the blood sugar was 330 mg per 100 cc. On discharge the patient was advised to take 36 units of protamine zinc insulin daily.

He was readmitted in November, 1941, complaining of edema of the ankle of several months' duration, dyspnea on slight exertion and orthopnea. The blood pressure was 180/106. Cardiac enlargement with an apical systolic murmur was found, and there was a small bilateral pleural effusion. The urinary sediment contained many white cells, and a

phenolsulfonephthalein test showed 19 per cent excretion of the dye in 2 hours. The congestive failure responded to rest and digitalis therapy, and he was discharged in fairly good condition on November 29, only to be readmitted 16 days later with nausea and vomiting, slight mental confusion and dizziness. Spinal-fluid examination revealed a total protein of 60 mg per 100 cc but was otherwise negative. The blood nonprotein nitrogen was 51 mg per 100 cc, and the urinary sediment showed 20 to 30 white cells per high power field. The total protein was 5.5 gm per 100 cc. He improved and was discharged on January 3, 1942, although the ankle edema continued.

The final admission occurred only 3 days after discharge, when the patient again complained of nausea and vomiting, drowsiness and headache. The urine contained innumerable white cells, and there was a large trace of albumin. Examination of the blood disclosed a red-cell count of 3,800,000, with a hemoglobin of 12.2 gm per 100 cc, and a white-cell count of 10,400. An electrocardiogram revealed low T waves and small QRS complexes, suggesting myocardial damage.

The patient improved strikingly and was ready for discharge on February 5, when he suddenly developed marked dyspnea and cyanosis and collapsed. He died within 10 minutes.

Autopsy revealed a terminal massive pulmonary infarction. The right foot showed histologic changes similar to those previously found in the left foot but without evidence of infection. A partial loss of bone structure, with evidence of bone absorption was seen, with a loss of joint spaces.

DIFFERENTIAL DIAGNOSIS

It is believed that the bone destruction in these cases represents a trophic change resulting from diabetic neuropathy and is similar to the arthropathies that may result from neurosyphilis, syngomelia, nerve injuries and the neural form of leprosy. Since the neuropathic foot is painless, the patient continues to walk and hence to traumatize the softened bones, a deformed thickened foot resulting.

In view of the resemblance to the true Charcot joint of syphilis it is essential to distinguish the diabetic neuropathic foot from this condition. The differentiation is not always possible by x-ray examination alone.

The classic arthropathy of Charcot often begins as a sudden spontaneous swelling of the joint and is rarely preceded by injury or by pain. In the ninety-two joints in 70 patients reported by Key,⁸ injury had preceded the joint lesion in only 3 cases. The enlargement is due not only to an accumulation of fluid within the joint but also to periarticular swelling, which at times extends from the ankle to the knee. As the swelling increases, a feeling of tension and a variable amount of dull, aching pain in the joints may keep the patient awake at night. This acute stage may last for a week but subsequently subsides, with disappearance of the pain, and is succeeded by the chronic stage, in which the swelling is confined to the region of the joints and the disintegration of the joint progresses so that function is more or less impaired. Destruction and disintegration of the capsule and ligaments of the joint result in abnormal mobility. The articular cartilage is eroded, and the underlying bone may be eroded, with consequent fractures. Proliferation of cartilage and bone may occur, and there is often much thickening of the synovial membrane.

tube in place four and five days, respectively. There was no noticeable tissue reaction to the tube.

Poppe and de Oliveira⁶⁰ report that Polythene cellophane produced a marked fibrous reaction when wrapped around the aorta in experimental animals. This film caused more reaction than a commercial cellophane, which in the experiments caused little reaction. These workers used Polythene film to wrap around a syphilitic aneurysm to cause thicken-

Preliminary studies carried out to determine whether polyethylene had any inactivating effect on penicillin showed no significant diminution in the effectiveness of the drug after contact with sections of the tubing for twenty-four hours. Narat and Cipolla⁶¹ and Huelsebusch et al.⁶² reported a drastic reduction in penicillin activity after contact with certain plasticized forms of synthetic tubing, including Tygon and White Surgical Koroseal.

FIGURE 1

ing of the wall and obliteration of the aneurysmal sac. The use of the same material in aneurysms in 3 other cases and in a recurrent patent ductus arteriosus was mentioned, but none of the cases had been followed for a sufficiently long period to justify any conclusions. The experimental results of these workers are somewhat contrary to those of others reviewed below, particularly on the response to cellophane. They refer to Polythene cellophane or film, which in all likelihood was not pure polyethylene.

Ingraham, Alexander and Matson⁶¹ performed animal experiments to determine the reaction of cerebral tissue to polyethylene. Sections of pure polyethylene tubing of small diameter were buried in the cerebral cortex of cats, dogs, monkeys and rabbits. The animals were sacrificed at intervals of two to ninety days, and the cortex containing the polyethylene was submitted for histologic study. The amount of reaction to this plastic was slight, and the tubing was surrounded only by a thin fibrous tissue layer. Emphasis was placed on the importance of obtaining absolutely pure polyethylene for surgical use. A variety of products supplied to industrial concerns under the name of polyethylene and Polythene contain chemicals other than the pure polymer. These are in general irritating to human tissue and should not be employed. In brief, these studies indicate that pure polyethylene is well tolerated by the body, with a reaction similar to that following the use of methyl methacrylate.

None of the materials tested had any effect on streptomycin.

CELLULOSE PLASTICS

Cellophane

The cellulose plastics were among the first used in industry. In 1869 Hyatt laid the foundation for the modern plastics industry by mixing cellulose nitrate with camphor to form a plastic material. This product is at present called "celluloid" or "Pyralin." Many chemical modifications of this substance were subsequently developed to form other plastic materials with desirable qualities. Cellulose acetate, a compound that is less inflammable, more durable and more easily molded than cellulose nitrate, is an example. Plasticizers are necessary to make these materials pliable, tough and durable.

One of the most important cellulose plastics is that known as regenerated cellulose, commercially called "cellophane." The chemical composition of the finished product is similar to that of the original cellulose from which it is derived. A complicated series of chemical reactions is necessary to produce this product, but in general the cellulose obtained from cotton or wood reacts with caustic soda and carbon disulfide to form cellulose xanthate, which on immersion in an acid bath is converted into regenerated cellulose. For many of the commercial uses of cellophane, impermeability to water is desirable. This is made possible by surfacing it with

✓ POLYETHYLENE

It has been known for many years that ethylene could be polymerized, but until 1936, when a new process involving high pressures was devised in England, only liquid and semiliquid polymers were obtained. Polyethylene was first employed experimentally in the United States in 1941.⁵⁷ The commercial use of polyethylene began here in 1943, when it was first produced in quantity.¹

Ethylene has a simple chemical structure, and polyethylene, which is a polymer of ethylene, is—theoretically, at least—the simplest structure in which a chain polymer can exist. It consists of carbon atoms joined in a chain, each one carrying two atoms of hydrogen. These chains, according to Bailey,⁵⁸ range in length from 200 to 1000 or more units.

Polyethylene (also called "Polythene") is a tough thermoplastic resin that has a slightly cloudy appearance. It is flexible, resistant to water and most other solvents and chemically inert. It maintains its toughness over a wide range of temperatures. None of its characteristics change within the extent of human body temperatures. It is tasteless and odorless. It is light, with a specific gravity of 0.92–0.95. By a method known to the plastics industry as extrusion, the material can be formed into rods, tubes, sheets or films. In the process of extrusion polyethylene is supplied in bulk form to a cylinder. Under pressure and heat within the cylinder, the final product is extruded through an aperture in the desired form (Fig 1).

One of the most desirable qualities of pure polyethylene from the point of view of use in the body is its flexibility without the addition of a plasticizer. On theoretical grounds because of its chemical inertness, simple chemical structure, resistance to water and pure state, this material should be well tolerated by tissues.

Polyethylene has found little place in medicine and surgery to date, but its flexibility, transparency and toughness and the facility with which it can be made into any size of tube or any thickness of film suggest multiple uses in the field of surgery.

Several possible drawbacks to the surgical applications of polyethylene should be mentioned. Since it is widely employed in industry because of its electric-insulating characteristics, manufacturers sometimes further enhance these properties by the addition of other chemical substances, known as antioxidants. Because one rarely knows what the added substances are, they must be considered harmful to the body unless proved otherwise. In obtaining this material, *pure* polyethylene should be specified. Manufacturers also state that polyethylene is occasionally extruded through a machine that has previously been used to extrude another substance containing a plasticizer or another chemical compound. It is apparently difficult to free the extruding apparatus completely of these substances, and for commercial use this is rarely necessary. Consequently, if this material is to be employed in surgical procedures, it is advisable to test small portions in experimental animals to be certain that it does not contain added chemicals irritating to the body. The material might, if found useful in a variety of surgical procedures, be dispensed by commercial medical-supply houses, which could take the responsibility of supplying a pure product.¶

Polyethylene will not tolerate sterilization by autoclaving, but it can be sterilized by boiling. It tends to retain the curve or shape in which it is placed during the process of boiling. Chemical sterilization by immersion in a 1:1000 solution of Zephiran for eighteen hours has been found satisfactory provided care is taken to see that the solution reaches the lumen of the tube and that the plastic, which is lighter than water, is kept completely in the solution and not floating on the surface.

Meyers⁵⁹ described a procedure of inserting a piece of small-caliber polyethylene (Med-O-Seal) tubing into a vein through a needle. This has provided a satisfactory method of giving repeated or constant intravenous injection through the same tube over prolonged periods without immobilizing the arm or leg. If intermittent injections are required, the tube is filled with physiologic saline solution at the completion of each injection, and the open end is plugged. Clotting does not take place within the tubing by this method, which Meyers used in 9 cases, in 2 of which he left the intravenous

¶Polyethylene is now furnished by A C Balfour Associates, Englewood, New Jersey as "Med-O-Seal."

ense reaction occurred consisting in a collection of gelatinous or purulent fluid around which the fibrous tissue contained phagocytic mononuclear cells. A dense scar-tissue band was formed around the arteries wrapped with cellophane.

Gross,⁷⁴ in several of his early cases, wrapped the Pont P T 300 cellophane around the patent ductus arteriosus after it had been ligated. He found that the material aided in maintaining occlusion of the patent ductus arteriosus. More recently, he has found its use unnecessary, since he has been able successfully to divide and suture the ductus in the majority of the cases. The use of cellophane for this purpose has also been reported by Harper and Robinson,⁷⁵ and Harrison and Chandy⁷⁶ have employed it to occlude a subclavian aneurysm.

One can only conclude that cellophane is a strong tissue irritant and a potent stimulator of scar formation. There may be, and probably are, certain types of cellophane that are less irritating than others, but all experimental and clinical work that has been accompanied by adequate histologic studies confirms the conclusion that the material is irritating in the body. Its use, therefore, should be limited to the laboratory or to clinical cases in which a localized layer of scar tissue is desirable for therapeutic reasons.

Celluloid

Closely allied to cellophane chemically is another cellulose derivative, cellulose nitrate, mentioned above. This is better known by its trade name of "celluloid." As a general rule, camphor is used as a plasticizer for cellulose nitrate to produce the finished product.

For twenty years after World War I, sporadic reports of the use of celluloid as a material to fill skull defects appeared. An adequate review of this subject has been made by Grant and Norcross,⁷⁷ who found the material unsatisfactory in their own small series. In 1 case the celluloid plate was removed because of postoperative headaches. It was found to be enclosed in a sac formed by the pericranium and adherent to both pericranium and dura. The authors stated that the membrane was "several millimeters thick and was intimately connected with the dura, from which it was peeled off in layers until healthy dura was reached."

Ney⁷⁸ reported the use of celluloid in cranioplasty in 300 cases, with satisfactory results. He stated that there were infections in only 5 cases, although in all cases drains were left in the wounds for forty-eight hours and in most cases fluid continued to form over the plates for days or weeks. There were no histologic studies in this series, and there was no mention of a long-term follow-up study in any large percentage of the cases.

Woolf and Walker¹¹ reviewed the subject of cranioplasty and concluded that celluloid causes a moderate tissue reaction but that many such plates have

remained in place for long periods. They stated that the material became brittle and friable after prolonged periods in the body. In view of the more recently developed alloplastic grafts that have proved easier to handle and are better tolerated by the body than celluloid, there seems little need for its use in cranioplasty.

MISCELLANEOUS PLASTICS

In addition to the plastics described above as attaining relatively wide fields of usefulness in surgery, isolated reports of studies with other materials are found in the literature. In general, such reports illustrate the clinical use of plastics that seem to have desirable physical properties, without well controlled experimental or follow-up studies. Smith-Petersen⁷⁹ used a bakelite mold as a hip cup in an arthroplasty. The patient was reported as benefited when last seen two years after the operation. Bakelite is one of the organic synthetic resins of the phenol-formaldehyde group, so far as can be determined, no study of the response of tissue to such compounds has been made.

Baker⁸⁰ reported a new type of plastic hip cup for arthroplasty but did not mention the type of plastic used. He was primarily concerned with the form that the cup should assume in relation to the head of the femur.

Bellas⁸¹ described histologic studies of a suture material called "Plastigut," which he described as a polymerized condensation product of aliphatic and aromatic alcohols with short-chain aliphatic aldehydes. The material was further described as a nonreacting, nonabsorbable, noncapillary suture that was satisfactory in surgical procedures. The histologic sections displayed showed little tissue reaction to the Plastigut.

Blaine⁸² made various plastic materials out of casein, fibrin and other protein products. These plastics were formalized for varying periods. They were buried in the long bones of rabbits and studied at intervals. The protein plastics were all completely absorbed, the rate of absorption being inversely proportional to the degree of formalization. They maintained strength for only three or four weeks. Blaine noted that the breakdown of the proteins was probably "responsible for the heavy cellular infiltration commonly noted at an intermediate stage at the margin of the softened plastic." Nevertheless, he considered these plastics well tolerated. He did not believe that such products as he used were suitable for use in human subjects.

To illustrate the difficulty occasionally encountered in carefully delineating the field of plastics, reference should be made to methyl cellulose, which is manufactured industrially as a mucilage and is soluble in cold water, giving a water-clear, viscous colloidal solution. It has been described as a methyl ester of cellulose and consists of a long chain of dextrose molecules. Hueper, Martin and Thompson⁸³

a thin film of cellulose nitrate lacquer. Cellophane is formed in thin transparent sheets that are used for many purposes, prominent among which is the wrapping of packages of cigarettes.

Cellophane, with its smooth surface, pliability, toughness and transparency, has attracted the attention of many surgeons. Its properties invite its use in the human body as a covering or sheath where the normal coverings are lost.

Perhaps nowhere in the medical literature are there sharper contradictions regarding the reaction of a given material in the body than in the articles on cellophane. Some authors have maintained that it causes little or no reaction, whereas others have found that it incites an intense tissue reaction. One of the inherent difficulties has been the negligence of some of those who have reported on the use of cellophane to specify exactly what type they used. There are several different products, some treated with other chemicals to make them impervious to water. Probably many workers who have used these products with conflicting results have employed dissimilar chemical materials.

Another difficulty arising from the use of cellophane in surgery is the inaccessibility of information regarding plastic products from the manufacturers themselves. Chemicals may be used to treat plastics that are considered trade secrets by the industrial concerns that produce them. In general, the reports that cellophane is well tolerated by the body have been based on a few clinical trials unsupported by experimental work or histologic studies of tissues. The more careful studies of cellophane have shown it to incite such a foreign-body response that this particular quality has been used in unusual circumstances when intense scarring is desired.

Wheeldon⁶³ used cellophane that he designated "No 300, moisture-proof, transparent film, 0.00088 inches thick." He performed a hip and a knee arthroplasty in which this material was employed as an interposition membrane, and the substance was also used in a tendon operation as a sheath. All the patients were reported to have benefited by the operations, and Wheeldon considered cellophane reactionless. No tissue-reaction studies were reported.

In like manner, McKeever⁶⁴ used No 300 cellophane in 4 cases as an interposition membrane in synovectomy, and considered it satisfactory. Harley and Breck⁶⁵ employed cellophane from cigarette packages in joint and tendon operations. They sterilized the material by boiling for twenty minutes and later "wiped off the waterproofing material." The patients were followed for only a few weeks and were reported as much improved by the operations.

Donati,⁶⁶ in Italy, used a commercial cellophane to replace the dura in a series of animal experiments. He reported that the brain showed no unusual reaction and that no adhesions were formed between the cerebral cortex and the material. The exact

type of cellophane employed was not recorded and there was no mention of its use in human patients.

In the Russian literature, Christyakov⁶⁷ recommended the utilization of cellophane as a protective covering over open or infected wounds. In the same communication, cellophane was reported to be satisfactory as a sheath around the anastomotic site in peripheral-nerve sutures. It had been used in 9 cases, as well as in 2 tendon operations. In the nerve anastomoses in 2 cases and in both the tendon cases, it was subsequently necessary to remove the cellophane, presumably because of infection.

In addition to the papers mentioned above, Poppe and de Oliveira⁶⁸ recently published an article describing experimental attempts at occlusion of vessels with various plastic materials. They reported the use of "No 300 P N T 71" and "No 300 P T 62" cellophanes, which, they stated, are cellulose hydrate, nonmoisture proof and insoluble in water and dilute acids. They were said to produce little reaction when wrapped around the aorta of an experimental animal. No other mention was made of the type of reaction and no photomicrographs were shown, but the efficacy of cellophane in producing scar around a major artery was less than that of other materials used, including Polythene film.

In sharp contrast to the reports of authors who consider cellophane well tolerated by the body is a series of papers, most of them the accounts of careful experimental, clinical and histologic studies, condemning the material as an irritating foreign body or recommending it for use in tissue because of its ability to stimulate the formation of scar tissue. Indeed, as a result of work reported by Page,^{68, 69} Graef and Page⁷⁰ and Dunhue,⁷¹ the term "cellophane perinephritis" has been coined. This describes a type of dense scar tissue that forms around a kidney after a piece of du Pont P T 300 cellophane has been wrapped around it. This is a reliable method of producing experimental hypertension in animals. It causes an intense inflammatory reaction, with the attraction of many polymorphonuclear leukocytes followed by continuous fibroblastic activity and deposit of collagen. The cellophane does not disappear, and the response lasts as long as there are cells and vascular channels around the cellophane to permit reaction. This type of reaction of tissue to the material has also been found by Bailey and Ford,⁶¹ who buried cellophane in the abdominal wall of guinea pigs and studied histologic sections of the tissue removed at various intervals.

Following the work of Page,^{68, 69} Pearse^{72, 73} studied the experimental occlusion of large arteries in animals by the use of du Pont P T 300 cellophane. In several animals complete closure of the aorta was obtained by this method. Pearse observed that this material was an extreme tissue irritant, since an in-

Adequate experimental trial should precede the clinical use of any untested plastic material in surgery

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

Weekly Clinicopathological Exercises

FOUNDED BY RICHARD C CABOT
TRACY B MALLORY, M.D., Editor
BENJAMIN CASTLEMAN, M.D., Associate Editor
EDITH E. PARRIS, Assistant Editor

CASE 33111

PRESENTATION OF CASE

A thirty-seven-year-old Swedish asbestos worker entered the hospital because of cough and chest pain

Two and a half years before admission the patient had developed a cough, nasal congestion, nasal discharge, fever and shortness of breath that had persisted one week and had been followed by a dull, aching pleuritic pain along the left costal margin

He was hospitalized for a week and then rested at home for four months

In the hospital about 1000 cc of fluid was removed from the left side of the chest. Subsequently, he returned to work and felt well except for a morning cough productive of small amounts of odorless white sputum

Occasional chest pain and exertional dyspnea were also noted

A year and a half later there was an insidious onset of weakness and fatigability and a gradual loss of 25 pounds in weight

Three months before entry the pleuritic pains became persistent, and the weakness and dyspnea severe, and the patient slept propped on two pillows

Repeated sputum smears were negative for tubercle bacilli

The patient's work consisted in cutting asbestos insulating board, he denied exposure to undue

amounts of dust

There was no history of exposure to tuberculosis

Physical examination revealed the patient to be orthopneic and breathing rapidly at a rate of 30 per minute, with a dry, hacking cough and clubbed fingers

There was a slight, shotty, generalized lymphadenopathy

Respiratory expansion on the left was diminished, as were tactile and vocal fremitus and breath sounds

On the right there were increased bronchovesicular breath sounds and scattered dry rales

The heart and mediastinum were shifted to the right, and the apical beat was maximal in the right midclavicular line

There was a ticktack rhythm with a rate of 110, and a pulsus paradoxicus

The abdomen was normal

The temperature was 100°F

The blood pressure was 128 systolic, 70 diastolic

Examination of the blood disclosed a red-cell count of 4,900,000 and a white-cell count of 12,200, with 77 per cent neutrophils, 16 per cent lymphocytes and 7 per cent monocytes

The urine and stools were normal

X-ray examination showed numerous discrete areas of increased density scattered over the right lung, pressing on the lower trachea and left main bronchus and deviating them to the right was a large mass measuring 11 cm in diameter (Fig 1)

A small amount of aerated lung was seen at the periphery of the mass

There was either fluid or, more probably, dense pleural thickening and collapsed lung between the mass and the lateral costal margin

The left lower-lung field was almost completely opaque

In the hospital the patient's condition became steadily worse

Further x-ray studies showed displacement of the esophagus to the right (Fig 2), extensive periosteal new bone formation of the left upper ribs, slight displacement of the stomach to

recommended it for use as a plasma substitute in place of acacia. It was fairly well tolerated in animals when given as a 2 per cent solution intravenously, but it has the disadvantage of being stored in the liver, spleen and kidneys. Presumably, since the advent of readily available plasma during and following World War II, it will not be widely used in blood-replacement therapy.

DISCUSSION

A factual review of the application of industrial plastics in the field of surgery has been presented. The tremendous variation in plastic materials, with the production of literally thousands of different types, is at first sight confusing, but on closer study it is evident that for the selection of materials to be buried in human tissues, certain definite criteria are necessary. Primarily, such criteria forbid the use of any plastic that can do harm to the body either by toxicity or by irritating properties causing excessive scar-tissue formation. There are certain exceptions to this rule in the use of materials to cause the formation of a localized area of scar tissue, as in the obliteration of a patent ductus arteriosus or the surgical treatment of aneurysms, but the exceptions are few and well known.

Choosing industrial plastics for use in surgery is therefore much more than a selection of certain materials that possess desirable physical properties. In general, plasticizers incorporated within plastics are not well tolerated by the body. The exclusion of all plastics containing plasticizers greatly narrows the field of selection, when the field has been further delineated by the requirements imposed by necessary physical properties for specific uses, a small number of plastic materials remain. From the review presented above, it is all too obvious that frequent clinical use of plastics has been made without any controlled studies. Consequently, many publications on the employment of plastics in surgery are merely the reports of the isolated use of some plastic material in clinical surgery.

In an attempt to be exact in the study of plastics, a difficulty is encountered — namely, the possession of certain commercial secrets by industrial concerns. As a result, in experimental work with plastics it is sometimes impossible to obtain information regarding the chemical make-up of the compounds used. Furthermore, the industrial utilization of plastics does not require the same purity as the surgical use of the same materials. If an apparatus employed to produce a plastic tubing, for example, has been previously used to produce some other material, it may contain minute quantities of irritating chemicals of no significance to industry but of potential harm in surgical procedures. This factor must be taken into consideration, particularly when plastic tubing such as polyethylene is employed. The dispensing of a standard product of

nylon sutures by medical-supply houses minimizes the importance of this point for such material. Methyl methacrylate can be easily polymerized as a pure chemical product with little danger of added chemical impurities. Cellophane is in no sense of the word a pure product, and in view of the fact that it should be used only where localized scar tissue is desired, the problem resolves itself into a search by the investigator for commercial brands of the product that are sufficiently irritating to the body for the desired use.

There are many obvious discrepancies in the medical literature dealing with plastics — disagreements that do not appear reconcilable. In the main, these discrepancies are based on the failure of some investigators to specify exactly the plastic product used in the work they have reported. In some instances it has been difficult, because of commercial secrets, to obtain detailed information, and in others it appears that impurities, of which the investigator was unaware, were included in the materials. Whatever the reasoning behind the reporting of the surgical use of plastics without exact knowledge of the plastic, the practice of choosing such materials for clinical trial because of their desirable physical properties alone should be abandoned. Sufficient knowledge regarding plastics is now available to enable one to choose a material that is well tolerated as well as one that possesses desirable physical properties. If other materials are needed, or if promising new plastics appear, their clinical use should be preceded by adequate experimental study.

Three plastic materials have been found to be well tolerated by the body, and in aggregate they offer an imposing list of desirable physical properties from which a selection can be made for surgical use. Methyl methacrylate (Lucite, Plexiglas), a pure polymer that is hard, transparent, and easily cast into desired forms, can be used for cranioplasty, for implants in various parts of the body and in the form of rigid tubes. Nylon, in the form of a filament, is at present employed only as a suture material. Polyethylene (Polythene) is a polymer of simple chemical structure that is pliable, soft and relatively transparent. Its primary value has been in the form of tubing.

SUMMARY

A review of the medical literature regarding industrial plastics is presented. Three plastic materials are well tolerated by the body: methyl methacrylate (Lucite, Plexiglas), nylon sutures and polyethylene (Polythene).

Cellophane is in general a severe tissue irritant, of use in surgery only to incite scar tissue.

A variety of other plastic materials have received sporadic clinical trial but are not recommended.

the left lung or from a mediastinal tumor. I should like to ask Dr. Schatzki whether he has ever seen rounded shadows of this size and density that were not due to tumor.

DR. RICHARD SCHATZKI: Yes.

DR. KING: I stand corrected on that point.

DR. SCHATZKI: That does not mean that this was not a tumor.

DR. KING: I have never seen rounded shadows of this size and distribution with silicosis, tuberculosis

air left in the left lung is the small amount seen in the left upper lung. The films do not show what is going on lower down.

DR. KING: So you will not help regarding the position of the tumor—that is, whether it is in the lung or outside the lung?

DR. SCHATZKI: I think that I could help if I was allowed to.

DR. KING: I think that it would be all right, how about it, Dr. Castleman?

FIGURE 2. Roentgenogram of the Chest and Abdomen following a Barium Swallow Showing Displacement of the Esophagus and Stomach by a Mass in the Left Side of the Chest.

or in fact anything, and I therefore believe that the process in the right lung was definitely a metastatic tumor. The x-ray film of the left side of the chest shows a large, round mass displacing the trachea and the left main bronchus to the right. Is the tumor in the lung itself or in the mediastinum?

DR. SCHATZKI: The same mass is visible on this film in the same position. I do not believe that one should try to delineate the exact outline of the tumor when so little air is present. Other criteria should be used to demonstrate the mass. The only

DR. BENJAMIN CASTLEMAN: By all means.

DR. KING: I need a great deal of help.

DR. SCHATZKI: There is some definite evidence of a large mass outside the lung. The first indication is the position of the esophagus, which is displaced far to the right side by a mass. This mass has a diameter much larger than the mass in the upper-lung field, and therefore it cannot be a tumor in the lung. The second point is the position of the fundus of the stomach, which is pushed downward in contrast to what one would expect with a lung tumor.

the left, enlargement of the spleen and the suggestion of a retroperitoneal mass rotating the left kidney. Three attempted thoracenteses failed to encounter fluid, although the needle was inserted to a depth of 5 cm. No acid-fast organisms were found in the sputum. Tuberculin tests were negative in a 1:1000 dilution. The patient became ex-

the final hospital admission, with fever for a week. About 1000 cc of fluid was removed, following which the patient was discharged from the hospital. He then rested at home for four months, returned to work and remained in good condition for a year. This could have been pleurisy with effusion, perhaps tuberculous. Many sputum examinations, however,

FIGURE 1 Roentgenogram of the Chest, Showing Opacity on the Left and Multiple Nodules in the Right Lung

tremely weak and dyspneic and perspired constantly. He died on the thirty-seventh hospital day.

DIFFERENTIAL DIAGNOSIS

DR DONALD S. KING: This seems to be the old problem of a tumor in the lung with a decision to be made regarding the kind of tumor. As in most cases, the decision will be based largely on the x-ray appearance.

One should comment first on the occupation. This man worked with asbestos, cutting insulating board. Exposure to asbestos causes lung changes but never, in my experience, to the extent that was present in this case. I believe that asbestosis was not a factor in the illness and that, if present, it was of secondary importance.

The next question concerns tuberculosis. The onset of the disease was two and a half years before

showed no tubercle bacilli, and shortly before death a tuberculin skin test was negative in a 1:1000 dilution. In any event, the evidence for tuberculosis does not seem sufficient to justify that diagnosis in addition to what I believe was a tumor. My diagnosis is tumor, with fluid that was secondary to the tumor and not due to tuberculosis or other infection.

The x-ray films present a different picture on each side of the chest. On the right side there are many nodules, which are better shown in some films than others. In my experience, rounded nodular shadows of this sort have always been caused by metastatic tumor, either from some spot elsewhere in the lung or from some place outside the chest. If the tumor was metastatic from outside the lung, it could have been from above the clavicles or below the diaphragm, or there could have been metastases from a primary bronchiogenic cancer in

oses of x-ray therapy were given, without effect in the lesion. We were able to get a needle biopsy shortly before death. A mass developed above the left clavicle about 5 cm in diameter, and we thought that there was also a mass in the epigastrium.

DR KING: Such metastases would be against my diagnosis. A primary carcinoma of the lung would be likelier to metastasize to the neck, although lymphoma could do so.

CLINICAL DIAGNOSIS

Carcinoma of lung, probably metastatic

DR KING'S DIAGNOSIS

Mediastinal teratoma, with metastases to right lung

ANATOMICAL DIAGNOSIS

Mesothelioma of pleura and pericardium, with metastases to right lung and retroperitoneal lymph nodes

PATHOLOGICAL DISCUSSION

DR CASTLEMAN: The left lung was completely encased on all sides by a thick, hard, somewhat

from any parenchymatous tumor nodules. The heart and pericardium together weighed 1100 gm. The heart itself was perfectly normal, the increase in weight being due to the tremendous thickening of the visceral pericardium, which measured as

FIGURE 4 Photograph of the Heart Showing Neoplastic Involvement of the Visceral Pericardium

much as 3 or 4 cm in thickness (Fig 4). This gross picture of involvement of the pericardium and

FIGURE 3 Photograph of Coronal Section of the Left Lung, Showing Complete Encasement by the Pleural Tumor

shiny, fibrous tumor compressing the lung into a small fraction of its normal volume. In places this thickening of the pleura or tumor tissue involving the pleura measured as much as 8 cm (Fig 3). There were multiple tumor nodules in the right lung, but no involvement of the pleura. This was in sharp contrast to the left lung, which was free

FIGURE 5 Photomicrograph of the Mesothelioma

pleura fits in with the diagnosis of mesothelioma. We examined the bronchi carefully throughout the left lung and found no evidence of tumor within a

that has produced collapse. Thirdly, the ribs, if anything, are spaced farther apart than on the normal side, which is again unusual for a lung that has collapsed.

DR KING I should have committed myself before I asked that question, but I agree with your conclusions. I cannot be sure that this was not a bronchiogenic carcinoma of the left upper lobe, but my opinion is against that diagnosis. There was also involvement in the left lower lobe. I suppose that this also may have been a tumor. Do you want to commit yourself on that, Dr Schatzki?

DR SCHATZKI I think that I know the answer. It is obvious, as I have said, that there was something outside the lung, otherwise, the stomach would not have been displaced or the ribs separated.

DR KING Do you think that it was a tumor or fluid?

DR SCHATZKI I believe that it was a tumor.

DR KING That is what I believe.

Let us go down to the abdomen. Was the spleen enlarged or was it displaced downward? I should like to omit the spleen if I may.

DR SCHATZKI So far as I am concerned, it may be excluded.

DR KING Was the stomach involved?

DR SCHATZKI There is no evidence of involvement of the stomach. It was displaced, but this was due to the low position of the left leaf of the diaphragm.

DR KING Was the liver enlarged? And was the displacement of the stomach to the left due to such enlargement?

DR SCHATZKI The liver was not enlarged so far as I can tell.

DR KING This is an intravenous pyelogram showing a retroperitoneal mass rotating the left kidney.

DR SCHATZKI Both kidneys are low in position, and I am wondering if what we see is not again due to the low position of the diaphragm.

DR KING You do not see the retroperitoneal mass?

DR SCHATZKI Not that I can be sure of. I do not see the outline of the kidneys so well as I should like to. The upper pole of the right kidney is clearly seen, but the upper pole of the left kidney is not.

DR KING I suppose that you have helped all you can. Do you want to say anything more?

DR SCHATZKI Yes, there are some rib changes.

DR KING You mean the periosteal changes in the rib? I have seen such changes only with pus. Have you seen periosteal changes with large tumor masses?

DR SCHATZKI We have seen them in patients who did not have empyema but who had a chronic nonspecific process in the lung.

DR KING The films show the periosteal changes clearly, and I am inclined to agree.

Actually, we have no evidence of any source of

tumor outside the chest, but the possibility of tumors in the pharynx and the thyroid gland should be mentioned because findings similar to those in this case follow metastases from malignant tumors in those areas. We are not justified, however, in making such a diagnosis with the evidence at hand. Below the diaphragm there is no indication of disease of the stomach, pancreas, liver or kidney. These films at first suggested that the testicle or the prostate was the primary source, or perhaps a so-called "hypernephroma." This is a fairly characteristic picture for metastases from the testicle or prostate, but we have no evidence to make that diagnosis. There does not seem to me to be any justifiable source for the tumor outside the chest, and we are back to the problem of what this tumor was.

Was it bronchiogenic or mediastinal? We have seen exactly this picture with teratomas of the mediastinum that have eventually broken loose. If it was a lung tumor I lean toward a bronchiogenic carcinoma with metastases to the right lung and possibly the retroperitoneal area. The findings were not quite consistent with those of bronchiogenic carcinoma because such tumors are usually not large enough to push the mediastinum to the other side unless a great deal of fluid is present. Also, the rib changes were more like those with a large tumor mass that had been pressing on that area for some time. The process had been going on for perhaps two and a half years. My diagnosis is a mediastinal tumor, probably a teratoma, with metastases to the right lung. I do not believe that the tumor was a lymphoma, although again that must always be considered. I doubt whether it was a bronchiogenic carcinoma with metastases.

DR F DENNETTE ADAMS How do you exclude lymphoma?

DR KING I do not exclude it. I have not seen x-ray findings such as these with lymphoma, which usually causes more symptoms than this man had for two and a half years. The other conditions I have named seem likelier.

DR ALFRED KRANES Is it not unusual for fluid due to tumor to subside for so long a time?

DR KING Yes, that is one of the things against trying to explain the whole picture as tumor. I agree that subsidence of all symptoms for a year after the removal of 1000 cc of fluid in a case of tumor is not usual. I wanted to make the diagnosis of tuberculosis, but I could not.

DR CHARLES L SHORT I saw this patient on the ward, and I went through much the same line of reasoning as Dr King has. From the history my impression was tuberculosis, but from the x-ray findings that certainly could not have been the primary diagnosis. I do not believe that most of us went so far as Dr King in being willing to say that the tumor was primary in the chest. We thought of lymphoma and for that reason small

chloride content was 301 and the chloride 91 milliequiv per liter. The prothrombin time was 8 seconds (normal, 14 seconds).

The urine was acid, had a specific gravity of 1.026 and gave a +++ test for albumin. It did not contain sugar or diacetic acid. The sediment showed many hyaline and some granular casts, as well as 6 white cells per high-power field. X-ray films of the chest and stomach showed the diaphragm to be high in position, and there were segmented areas of atelectasis in the left lower lobe. The stomach was greatly distended by gas. The small intestine contained a moderate amount of gas but was only slightly dilated. The colon was not distended, but the right side contained a large amount of fecal material.

During the day the patient gradually became drowsy. She was given 1500 cc of 5 per cent dextrose in physiologic saline solution and 900 cc of 5 per cent dextrose in water, and administration of 100,000 units of penicillin every three hours was begun. In the afternoon the chloride had fallen to 74 milliequiv per liter. The patient was cold and clammy and appeared sicker, although the abdomen was softer and peristalsis was improved. The blood pressure was 160 systolic, 90 diastolic, and the pulse was strong. The cecostomy drainage was 475 cc. The urine output had fallen off, although the actual amount was not recorded.

On the third hospital day the patient seemed somewhat more alert. The abdomen was much softer, and peristalsis was fairly good. The heart sounds, however, were distant, with a ticktack rhythm. The hematocrit was 57. The protein was 8.5 gm, the nonprotein nitrogen 155 mg and the blood sugar 200 mg per 100 cc, the chloride was 85 and the carbon dioxide 30.8 milliequiv per liter. The patient was given 3000 cc of 5 per cent dextrose in saline solution and started on 8 units of insulin. The cecostomy drainage was 230 cc.

On the fourth hospital day the temperature rose to 105°F, and the patient became incoherent and restless, with muscle twitching. The hematocrit was 56. The chloride was 92 and the potassium 2.5 milliequiv per liter, the nonprotein nitrogen 150, the calcium 7.7 and the blood sugar 308 mg per 100 cc. An electrocardiogram showed a sinoauricular tachycardia at a rate of 125. There were low T waves and moderate left-axis deviation. The chest leads showed a low T wave in Lead CF. The patient was given 20 cc of calcium levulinate without any effect on the muscle twitching. She also received 500 cc of 5 per cent dextrose in physiologic saline solution, 500 cc of whole blood and 2500 cc of 5 per cent glucose in half-strength physiologic saline solution. Nevertheless, she gradually relapsed into coma, and by evening the temperature had reached 106°F. She died on the fifth hospital day.

DIFFERENTIAL DIAGNOSIS

DR WILLIAM W. BECKMAN: This case is a new experience for me because yesterday Dr. Castleman sent the clinical record of this patient to my office and said that I could read it. The record provided really only one datum that is not in the protocol. One gathered from a reading of the record — although it did not state definitely — that a Levine tube had been present in the stomach most of the time that the patient was in the hospital. There was constant drainage from the tube, although the amount is not stated.

DR JOHN B. MCKITTRICK: That is true.

DR BECKMAN: The point about this case that struck me when I first read the record was that the patient apparently had no abdominal pain until six days before entry. Five days before its onset she was examined by a physician who knew her language, — she did not speak English, — and there were no abdominal complaints. She had had a rather abrupt onset of abdominal cramps and apparently went rather rapidly into collapse. X-ray studies revealed obstruction of the sigmoid, which either had become acutely obstructed or, it seems even more probable to me, had perforated and caused peritonitis. I believe that, instead of actual obstruction from a carcinoma, paralytic ileus was present. In any event it is clear that the patient had a carcinoma. There is no question that cecostomy was the indicated step.

The patient was admitted in coma and was known to have an elevated blood sugar, which brings up the possibility of diabetes. Another thing I learned from the record was that there was practically no acetone in the urine. This fact and the carbon dioxide measurements are against diabetic acidosis as an explanation for the coma, indeed, the possibility of diabetic acidosis can scarcely be entertained. The patient probably had the type of acidosis associated with arteriosclerosis in old people, which does not, so far as I know, produce coma. She had diabetes. One cannot be certain, however, how severe the diabetes was because in the hospital she was given injections of glucose that may have contributed to the elevation of the blood sugar.

The significance of the urinary findings is difficult to evaluate. The urine was said to have been normal when the patient was in the outside hospital. She had only one specimen here, which showed casts and albumin and which probably represented a certain amount of kidney disease, probably so-called "vascular nephritis." How much this contributed to the elevated nonprotein nitrogen is difficult to evaluate, because extrarenal factors must be considered.

Another point that was not mentioned in the protocol or the record is that the patient apparently had a fairly adequate urinary output during most of the hospital stay. In spite of this there was

bronchus, near a bronchus or in the lung itself. The nodules in the right lung were well circumscribed in the parenchyma away from the bronchi and were definitely metastatic. We were quite certain that we could rule out bronchiogenic or primary carcinoma of the lung. The bronchial lymph nodes contained no tumor. We searched every organ for a primary source, but we were unable to find any.

The histology of the tumor was typical of what has been described as a mesothelioma (Fig 5). The cells in some areas were cuboidal and arranged around fibrous stalks giving a pseudopapillary pattern. In other areas the cells were large, irregular and closely packed. Some were multinucleated, and others seemed to be forming mucinous material.

A number of papers have been written to the effect that there is no such tumor as mesothelioma of the pleura, that the cells lining the pleura do not form tumors and that these tumors really arise from a small focus in the lung. We have held a similar opinion for a long time. This is perhaps the first case in which we believed that there was actually such a tumor. It certainly fits in with most of the cases of mesothelioma of the pleura that have been reported.*

DR KING: I do not consider that it is fair to have given me a case with a diagnosis against which you, as pathologists, have been talking for twenty years. I could never make Dr Mallory accept a diagnosis of mesothelioma of the pleura.

DR CASTLEMAN: He has been sold on this one. The lesion in the abdomen was retroperitoneal tumor, but there was no tumor elsewhere.

DR ADAMS: What was the large lesion in the left lung?

DR CASTLEMAN: It was merely nodularity due to the pleural tumor.

*Klemperer, P., and Rabin, C. B. Primary neoplasms of pleura. *Arch Pathol* 11:385-412, 1931.

CASE 33112

PRESENTATION OF CASE

A seventy-two-year-old Polish housewife entered the hospital in coma.

Eleven days before entry the patient had received a slight back injury in an automobile accident. A physician examined her at that time and found only slight spasm along the lumbar muscles. Three days later the physician was called again because the patient complained of slight bleeding supposedly from the vagina, he could find no evidence of bleeding. Six days before entry the patient began to have frequent episodes of abdominal cramps. These continued daily. Three days later the abdomen was distended, with marked tenderness and a mass in the right lower quadrant. The patient was taken to another hospital, where a

plain film of the abdomen and a barium enema showed an abrupt, shelf-like obstruction in the lower sigmoid, with a markedly dilated large bowel, particularly on the right, and beginning small-bowel dilatation. Routine urine examinations were said to have been negative. There was a slight leukocytosis, and the blood sugar was 196 mg per 100 cc. On the following day the patient appeared acutely ill. The abdomen was greatly distended, and the patient complained of abdominal pain. No organs or masses could be felt. The pulse was about 115. On the same day an emergency cecostomy was performed under a local anesthetic. There was an increased amount of clear, straw-colored fluid in the peritoneal cavity. The colon and cecum were greatly distended, and a large amount of fluid and gas was removed by trocar suction. A glass Mixer tube was fixed in place by sutures. Following the operation the patient was said to have improved for a while, but the abdominal symptoms subsequently reappeared. She was transferred to this hospital on the afternoon of the second post-operative day.

The patient was known to have hypertension. A sister had diabetes.

Physical examination revealed an obese, disoriented woman. The left border of the heart extended beyond the midclavicular line, but the heart sounds were normal. There were coarse rhonchi, which cleared on coughing, in both lower lobes. The abdomen was distended, tense and slightly tender. Peristalsis was limited to a few tinkles. The diaphragm was high on both sides but moved to percussion. The cecostomy appeared to be functioning well.

The temperature was 100°F, the pulse 120, and the respirations 30. The blood pressure was 110 systolic, 70 diastolic.

A Levine tube was passed immediately on entry, and 500 cc of brownish fluid, as well as considerable gas, was aspirated from the stomach. The patient also received 600 cc of 5 per cent dextrose in water and oxygen. During the night she became extremely disturbed, tore up the oxygen tent and pulled out the intravenous drip and stomach tubes. The cecostomy drained 1680 cc of fluid, and 646 cc of urine was passed on the first hospital day. On the morning of the second hospital day the distention appeared to be slightly less, and peristaltic tinkles were somewhat more frequent. The tongue was dry.

The temperature was 102°F, the pulse 130, and the respirations 30. The blood pressure was 100 systolic, 60 diastolic.

Examination of the blood showed a hemoglobin of 16.3 gm per 100 cc, a hematocrit of 50 and a white-cell count of 9700, with 85 per cent neutrophils. The total protein was 8.5 gm and the non-protein nitrogen 100 mg per 100 cc, the carbon

etermination was made here, but I think that it was everyone's impression who followed this patient that the renal function was reasonably good until terminally, when the urinary output suddenly dropped and the patient excreted practically no urine

CLINICAL DIAGNOSES

Carcinoma of sigmoid, with perforation
General peritonitis

DR BECKMAN'S DIAGNOSES

Carcinoma of sigmoid
Intestinal obstruction (? paralytic ileus or mechanical)
Peritonitis
Mild vascular nephritis
Diabetes mellitus
Severe dehydration
Alkalosis

ANATOMICAL DIAGNOSES

Colloid carcinoma of sigmoid, with perforation and localized peritonitis
(Electrolytic imbalance, with renal insufficiency)

PATHOLOGICAL DISCUSSION

DR TRACY B MALLORY Autopsy showed some of the obvious things that were predicted. There was a carcinoma of the sigmoid, and there was also extensive diverticulosis of the same area. The large bowel was full of feces despite the cecostomy. The peritoneal cavity showed fresh, rather loose adhesions that were probably due to the cecostomy operation a few days earlier. There was no generalized peritonitis. The carcinoma and the area of bowel immediately around it were necrotic and pulled apart in the prosector's hands as he was dissecting it. Although there was a localized sepsis, there was no general peritonitis.

I think that the major question of interest concerns the kidneys in that there seemed to be so much functional evidence of renal insufficiency —

they showed practically nothing. The proximal convoluted tubules were swollen, and occasional loops of tubules revealed albuminous degeneration. It was the extremely mild nephrosis that Fahr* would have described as Grade I nephrosis when he wrote his monograph. I gather from the autopsy findings that the nitrogen retention and other changes were, as Dr Dole suggested, prerenal rather than renal. I do not believe that the renal lesions can even remotely explain the functional findings.

DR BECKMAN I should like to emphasize again that I still believe that the fluid administration was carried out with the proper restraint. I do not believe that one can stress the point too strongly that in a person with high blood pressure and hypertensive heart disease the administration of intravenous fluid and transfusions are apt to cause pulmonary edema. This is due to the development of acute left ventricular failure, with resultant congestion of the lungs.

DR LEONARD P ELIEL What do you think about the administration of 1.8 per cent of physiologic saline solution in a case of this sort to make up the salt deficit and not give too much fluid?

DR BECKMAN I suppose that that would be wiser. I have not had any experience with such therapy.

DR MCKITTRICK I had a rather uncomfortable experience in a similar problem with a chemical imbalance, but in this case there was small-bowel obstruction. The patient was a seventy-five-year-old woman. We gave 1.8 per cent sodium chloride solution, because she had a low chloride, and she went into severe pulmonary edema, which complicated therapy from that point on. Incidentally she also traveled the same path as the patient in the case under discussion. One must be careful about using concentrated saline solution in older people despite the chemical levels.

*Volhard, F., and Fahr, T. *Die Brightsche Nierenkrankheit*. 292 pp. Berlin: Julius Springer, 1914. P. 7.

evidence of marked depletion of the extracellular fluids, on the basis of the marked hemoconcentration shown by the elevated total protein, hemoglobin and hematocrit. There was a low chloride, a low calcium and a low potassium. For some reason there is no mention of the sodium. There was an elevated carbon dioxide content. All these things together indicate that the patient had lost a great deal of fluid from the upper gastrointestinal tract rather than from the cecostomy and that she had an alkalosis as a result of the removal of hydrochloric acid from the stomach.

I suppose that I was given this case to discuss the therapy, but I have always believed that this kind of exercise, in which the case terminates at autopsy, is not a satisfactory way of evaluating therapy. If we were to base an evaluation on such cases we should have to conclude that penicillin was of no value, and that is not quite true. The patient was desperately ill when first seen at the other hospital, and I give credit to everyone for the restrained but expeditious way in which the illness was managed. Every effort was made to correct the various surgical, bacteriologic and chemical abnormalities that were present. A cecostomy was performed to relieve acute large-bowel obstruction. Penicillin was given for what I think was peritonitis. The patient was given sufficient replacement fluid, but with restraint. Another point in the clinical record is that she was seen by Dr. Allan M. Butler, who thought the low potassium represented serious difficulty and suggested the intravenous administration of potassium. There is no way of knowing from the record whether potassium was given.

DR. MCKITTRICK: Potassium was not given.

DR. BECKMAN: It is difficult to administer a significant amount of potassium by vein, for high serum concentrations affect the myocardium and produce ventricular fibrillation. Perhaps with the low value it would have been proper to give a small amount, but potassium must always be given in concentrations not exceeding 4 to 6 milliequiv per liter — the normal value for serum.

DR. MCKITTRICK: I should like to say that Dr. Beckman is a good detective because he deduced all the omissions from the record with exact accuracy. The Levine tube was taken out forty-eight hours before death. His deduction regarding the electrolyte loss is correct, in that for practical purposes all the loss was from the Levine tube. The short history, so far as anyone could determine, is correct. The patient had symptoms for only six days prior to death, they consisted chiefly of abdominal cramps, which began suddenly.

The question of coma on entry is interesting. I did not believe that the patient was in coma. She was moderately irrational, although she did answer questions in her own language. If she was in coma

I do not know what kind, but it certainly was no diabetic coma.

The only blood sugar determinations that indicated a disturbance in glucose metabolism were the ones taken before entry and the one taken at the hospital before intravenous therapy was given. The urinary output was fairly good throughout the hospital stay, with the exception of the last twelve to fourteen hours, when it was markedly diminished — in fact, practically nonexistent. The sodium determination was not done purposely, Dr. Butler, who was called in to see this patient, did not believe that it would help a great deal in planning the treatment. An electrocardiogram was taken in an effort to determine whether there was any evidence of a low potassium, but we could not get any assurance on that score. The report on the determination of potassium came back twenty-four hours later. Despite the low value, Dr. Butler, who was handling that aspect of the therapy, was not quite ready to give intravenous potassium.

My point of view in the treatment of this patient was one of timidity. She was seventy-two years old and had hypertension, she was admitted with a low blood pressure and was probably a senile diabetic patient, as Dr. Beckman has deduced. There was tenderness only over the sigmoid — a point that is not mentioned in either the record or the protocol. At one time we believed that we had induced a certain amount of pulmonary edema with the intravenous therapy. We were cautious about giving potassium, but it may have been needed. All along the line we trailed the patient physiologically, we never did catch up with her. On the night of admission I hesitated to give saline infusion. Whether she should have had saline or something else, I did not know. Peritonitis appeared to be present — I could not understand the small-bowel dilatation, the tremendous dilatation of the stomach or the ileus on any other basis. This was an extremely perplexing problem throughout. All of us see cases like this once in a while, and do not know how to handle them. This is a good case in point because obviously we did not handle the problem correctly. I think that the autopsy findings will either help in the deduction of what should have been done or add further confusion.

DR. VINCENT P. DOLE: The single reported urine specific gravity of 1.026 suggests that the renal function was adequate and that the limitation in renal performance was due to extrarenal circulatory disturbances. It is conceivable that with this infection there was subsequent intrinsic renal impairment. Toward the end the apparently adequate renal output may have been misleading if the kidneys had lost their capacity to concentrate.

DR. MCKITTRICK: Several urine analyses were made at the other hospital. Incidentally, I was the surgeon who did the cecostomy. There was an adequate specific gravity. Unfortunately, only one

chronic illness or other cause and for the establishment of a retirement fund for the full-time employees of the Society. Furthermore, the report recognized the need of the Boston Medical Library for financial assistance and expressed the opinion that the library is an asset of the Society that should not be lost. In view of these facts, the committee recommended that the annual dues be increased to \$20.00, with the possibility that they might eventually be raised to \$25.00. The Executive Committee of the Council had approved the report and had made the following recommendations: that the annual dues for regular members be raised to \$25.00, that the rate become effective on January 1, 1948; and that of this sum, \$5.00 be earmarked for the Boston Medical Library. After a relatively short discussion, these recommendations, with two minor amendments, were adopted.

MORE PROTEIN FOR PREMATURE INFANTS

THE care of the premature infant constitutes, in pediatric practice, a particular problem by itself, with faithful attention to detail as the usual price of success. Three cardinal principles, with their ramifications, have long been recognized. These are maintenance of a suitable external environment, with special reference to temperature and oxygen content, protection against infection and suitable nourishment.

The necessity for the first two is in every case immediate, the third cannot be long delayed, and its problems are receiving renewed attention with recognition of the possibility that human milk is not necessarily the ideal food for the premature infant, regardless of the value it may have for the full-term infant.

Three Swedish investigators, Jorpes, Magnusson and Wretling,^{1,2} recognizing that the infant born several weeks before term has different nutritional requirements from the full-term newborn infant, have devised a supplementary food consisting of all the essential amino acids. The mixture used, made by the enzymatic hydrolysis of casein with pancreatic ferments, was added to human milk and in every case was followed by considerably greater gains in weight than those that were obtained with human

milk alone or when supplemented by unhydrolyzed casein.

Although these reports are among the first on the direct use of the amino acids to improve weight gain of premature infants, other writers have recognized the unusual needs of these patients for extra protein, calcium and phosphorus. Thus, Gordon and Levine,³ in 1944, stressed the wide variability in the nutritional needs of individual infants, whether breast or artificially fed, and pointed out the relative inability of premature infants to absorb fat, as evidenced by their frequent excessive loss of calories in the form of fecal fat. Not only are they apparently unable to utilize much fat, in which human milk is rich, but also they especially need protein, calcium and phosphorus, in which human milk is relatively low.

The implication is obvious: human milk, designed by Nature as a suitable food for the average full-term infant, must not be dogmatically and doggedly urged as the ideal food for all infants. Otherwise its employment needs no such unusual defense or apology as was offered by the medical student who, when required in an examination to state three particulars in which human milk is superior to cow's milk, wrote that it is cleaner, that it is more digestible and that it comes in more attractive containers.

SUBSCRIPTION TERMS: \$6.00 per year in advance, postage paid, for the United States (medical students \$3.50 per year); Canada \$7.00 per year (Boston funds); \$8.50 per year for all foreign countries belonging to the Postal Union.

MATERIAL should be received not later than noon on Thursday, two weeks before date of publication.

THE JOURNAL does not hold itself responsible for statements made by any contributor.

COMMUNICATIONS should be addressed to the *New England Journal of Medicine*, 8 Fenway, Boston 15, Massachusetts.

FEBRUARY MEETING OF THE COUNCIL

A STATED meeting of the Council of the Massachusetts Medical Society was held at the Boston Medical Library on February 5. Several matters of immediate interest to all members of the Society were discussed and duly acted on.

In the first place, the recommendation of the Committee to Nominate a Director of Medical Information and Education that Dr. John F. Conlin be appointed to this position was unanimously adopted. Dr. Conlin, who is thirty-eight years old, spent from 1926 to 1932 in a monastic order, he graduated from Boston College in 1934 and from Tufts College Medical School in 1938. After an internship at St. Elizabeth's Hospital and a residency at John Adams Hospital in Chelsea, he entered the Army in 1942 and was discharged

with the rank of colonel in 1946. During the last session of the Legislature he was extremely helpful in the fight against the Anti-Vivisection Bill. All in all, it appeared to the members of the committee that Dr. Conlin was highly qualified, by training, experience and attainment, for the new position, and the Council concurred. He is now attending courses at the Harvard School of Public Health and will assume office on or about July 1.

The second matter of importance concerned a recommendation by the Committee on Public Health that aggressive support be given to Commissioner Getting's program for improving conditions in state and local public-health departments. His proposals included higher salary levels for the professional personnel, the institution of a sanitary code, the subsidization of local health departments that meet established standards and the promotion of town unions of sufficient size to ensure support of modern public-health programs. The acceptance of this recommendation had not been approved by the Executive Committee of the Council, apparently because it was thought that the Society had no right to recommend salary increases for a particular group of physicians, and several councilors spoke in the same general vein. The discussion was concluded by Dr. Getting, who clearly outlined the difficulties that state and local health departments were encountering because of the inadequate salaries paid to professional workers and predicted a marked deterioration of such services unless something were done in the immediate future. He added that this directly concerned the health of the people of the Commonwealth, and that because of this, his program should be supported by the Society. The recommendation was approved by the Council with only a few dissenting votes.

Finally, the report of the Committee to Study Increase in Assessment of Dues was presented. It was brought out that the activities of the Society had greatly increased in recent years and that the sum needed to pay full-time and part-time salaries had proportionately grown. Attention was called to the need for a permanent headquarters for the Society, for some fund to aid the widows and children of deceased physicians, for one to help financially physicians who are incapacitated by

Number 12

SECOND-DAY ENCEPHALOGRAPHY, WITH PARTICULAR REFERENCE TO THE SIZE OF THE VENTRICLES*

RICHARD SCHATZKI, M.D.,† DONALD H. BAXTER, M.D.,‡ AND CHARLES E. TROLAND, M.D.§

THE literature contains a comparatively small number of publications concerning the appearance of the ventricles on the days following encephalography, although it is quite probable that a number of investigators have been interested in such follow-up studies without publishing them. Of the published reports, some were confined to the rate of absorption of air after encephalography,^{1,2} whereas others emphasized the importance of second-day studies for the demonstration of porencephalic cysts.^{3,4} Only a few observations were concerned with the size of the ventricles during follow-up studies, and those were quite contradictory. Schott and Eitel,⁵ as well as Reinberg,⁶ mention dilatation of the ventricles in later films as if it were a routine finding. This broad statement is made without any supporting evidence, no actual encephalograms are reproduced to illustrate this so-called "routine second-day enlargement." The explanation of Davidoff and Dyke¹—that these authors mistook the better visualized anterior horns for enlarged ventricular bodies—appears quite plausible. Friedman, Snow and Kasanin⁷ state that the shape of the anterior horns usually changes on the second day from the butterfly pattern to a more or less rounded form because of transitory internal hydrocephalus. This observation can apparently be explained on a basis similar to that mentioned by Davidoff and Dyke,¹ who state that there is no enlargement of the ventricles on the second day. Evans⁸ reported follow-up studies in 39 children, the majority of whom showed a slight increase in the size of the ventricles on later examination. In 7 cases there was a more striking increase in the size of the ventricles on the second day. Paul and Erickson,³ in a recent publication concerning second-day studies in 78

patients, found the ventricles usually decreased. Seven of the patients, however, showed an increase in the size of the ventricles on the second day. It was interesting to find that 4 of the 7 cases were post-traumatic, whereas 2 were cases of idiopathic epilepsy and 1 was a case of Alzheimer's disease.

During our encephalographic studies in a series of head injuries, some abnormalities were found that

FIGURE 1 Ventricular Measurements in the Anteroposterior View

The measurement of the width of the ventricle (a) was considered the most important of the measurements, it is the shortest distance between the lateral wall of the ventricular body and the superior medial corner of the ventricle.

led to a systematic examination of the skull on the days following the lumbar insufflation of air. We found definite enlargement of the ventricular bodies in a third of the group, the enlargement being extensive in some cases.

MATERIAL AND METHODS

Patients Examined

Among a large group in which encephalography was done, second-day studies were performed in 67 cases. In 60 cases, in which examination on the first

*Presented at the annual meeting of the Massachusetts Medical Society, Section of Radiology, Boston, May 23, 1946. Material collected at McGuire General Hospital, Richmond, Virginia.

§Senior resident in radiology, Shreveport Hospital.

Assistant professor of neurologic surgery, Medical College of Virginia, associate neurosurgeon, Medical College of Virginia Hospital.

the formal dedication of the Blood Processing Laboratory at 375 South Street, Jamaica Plain

Official opening of the Blood Processing Laboratory, the first state-operated laboratory designed specifically for large-scale blood processing and fractionation, will give physicians and others an opportunity to see in operation the equipment, methods and technics involved in mass production of blood derivatives. Staff doctors and technicians will be at hand to explain the work and to furnish any pertinent information desired by visitors. Glass-paneled refrigeration, sterilizing and filling rooms make it possible for onlookers to observe each part of the processing without the necessity of entering these rooms.

Although the occasion is primarily for the dedication of the new laboratory, the Antitoxin and Vaccine Laboratory will also be open to accommodate those who are interested in the preparation of the serums, vaccines and antitoxins that are manufactured there for distribution throughout the Commonwealth.

Open house will be held during the morning from 9 00 to 12 00, and in the evening from 6 00 to 9 00. Conducted group tours will be part of the activities of the day.

A cordial invitation to visit the laboratories is extended to all.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Nitrous Oxide-Oxygen Anesthesia. McKesson-Clement viewpoint and technique. By Major F W Clement, MC, A US, anesthetist to Toledo, Mercy and St Vincent's hospitals, Toledo, Ohio. Second edition, thoroughly revised. 8°, cloth, 288 pp., with 92 illustrations. Philadelphia: Lea and Febiger, 1945. \$4 50.

This new edition has been revised in the light of knowledge gained during World War II. During the period there have been no radical changes in either the agents used for anesthesia or their methods of administration, but much has been learned of the physiology of lowered oxygen tensions encountered in aviation. In this revised edition the changes are those of details rather than alterations of the original text. Changes and additions include the commonly accepted theory of nitrous oxide-oxygen anesthesia, with greater detail of its method of administration, the possible dangers associated with prolonged oxygen deficiency, the mechanism and treatment of shock, the role of carbon dioxide and of the sino-aortic areas and the compensatory reflex mechanism that protects the body in the presence of lower oxygen intake. The chapter on dental anesthesia has been enlarged to include more details on the use of the nasal-pharyngeal airway. This is a comprehensive monograph on its subject.

New Goals for Old Age. Edited by George Lawton. 8°, cloth, 210 pp. Second printing. New York: Columbia University Press, 1945. \$2 75.

This composite work brings together the various social and medical aspects of old age. The material was originally delivered as lectures in a course on mental health and old

age, under the Section on the Care of the Aged of the Welfare Council of New York City, during 1940-1941. The lectures are here brought together for the first time. An interesting final chapter is contributed by an aged woman who spent some of the happiest years of her life in a home for the aged. She is nearly eighty years old and entitles the chapter, "How it feels to be seventy-five and a woman." A bibliography of fifteen pages is appended to the text.

Bacillary Dysentery, Colitis and Enteritis. By Joseph Felsen, MD, director of medical research, Bronx Hospital, New York, and director, International and Pan-American Dysentery Registry. 12°, cloth, 618 pp., with 145 illustrations. Philadelphia: W B Saunders Company, 1945. \$6 00.

This monograph presents a correlated study of the historical, epidemiologic, clinical, pathological, bacteriologic, serologic and therapeutic aspects of bacillary dysentery. Dr Felsen is an authority on the subject, having dealt with epidemics, as well as clinical cases in their various manifestations. He established the International Dysentery Registry as a means of promoting co-ordinated study and preventive activity. He divides his subject into two main sections dealing with the acute and chronic forms of the disease and including chronic ulcerative colitis and chronic distal ileitis. An appendix is devoted to the technical methods used in the diagnosis of the disease. The last part of this chapter considers the prevention and control of bacillary dysentery and other infectious diarrheas. This is the first comprehensive study on the subject published in the United States. An extensive bibliography of ninety-six pages is appended to the text. This monograph should be in all medical libraries and in the libraries of physicians interested in the disease.

NOTICES

ANNOUNCEMENT

Dr Armand M Gamboa announces the removal of his office to 475 Commonwealth Avenue, Boston.

SOUTH END MEDICAL CLUB

The next regular meeting of the South End Medical Club will be held at the Sheltered Workshop of the Boston Tuberculosis Association, 35 Tyler Street, Boston, on Tuesday, March 18, at twelve noon. Dr John Homans will speak on "Arterial Deficiencies in the Legs in Middle and Advanced Age."

Physicians are cordially invited to attend.

AMERICAN COLLEGE OF CHEST PHYSICIANS

The oral and written examinations for fellowship in the American College of Chest Physicians will be held at Atlantic City on June 5. Applicants for fellowship in the College who plan to take these examinations should communicate at once with the Executive Secretary, American College of Chest Physicians, 500 North Dearborn Street, Chicago 10.

The thirteenth annual meeting of the College is scheduled to be held at the Ambassador Hotel, Atlantic City, June 5 to 8. The convocation for new fellows and life members of the college will be held on the first day of the meeting, when certificates will be awarded to fellows and life members admitted since June, 1946.

PRIZE CONTEST

The American Association of Obstetricians, Gynecologists and Abdominal Surgeons recently announced that the annual prize contest will be conducted again this year. Requests for detailed information should be addressed to the secretary, Dr James R Bloss, 418 Eleventh Street, Huntington 1, West Virginia.

(Notices continued on page xix)

entral ray in the vertical position. Anteroposterior, posteroanterior and lateral stereoscopic views represented the routine examination, additional films were taken in individual cases. The tube-film distance was held constantly at 90 cm, the projection in various positions was standardized as much as

cedures. On the basis of past experience, the size was first judged without measurement. The ventricles were classified as normal, moderately enlarged and enlarged and were then measured. Whenever possible the following separate measurements were made on the anteroposterior projection with

FIGURE 3 Case 1.
These films are first-day (upper) and second-day (lower)
posteroanterior views

possible. The first examination was made in the early hours of the afternoon. The second-day examination was usually done sometime during the forenoon, so that the actual time elapsed between the two examinations was between eighteen and twenty-two hours.

Various methods of measuring ventricles have been devised.^{1, 2, 3} We used two different pro-

cedures. In the horizontal position the distance between the superior medial corner of the ventricle and the convex lateral border of the ventricular body (Fig 1a), the distance between the superior medial corner and the superolateral corner of the ventricle (Fig 1b), and the distance between the superior medial corner of the ventricle and the concave lateral wall of the anterior horns (Fig 1c)

day was satisfactory and allowed comparison for follow-up studies, 35 patients had had open and 8 had closed head injuries and 7 had epilepsy, in 10, the examination was performed for other causes. In other words, a history of head injury was present in about two thirds of the cases. The interval between

30 to 45 cc of a 2.5 per cent solution being administered intravenously. The patient started to become active toward the end of, or immediately after, the completion of the examination. Two needles were introduced into the lumbar canal in two adjacent interspaces. About 20 cc of fluid was removed and

FIGURE 2 Case I

The lower film, an anteroposterior view taken on the second day, shows enlargement of both lateral ventricles, compared with almost normal-sized ventricles on the first day. There was a history of trauma four times in eight years, all of them due to automobile accidents, the last having occurred five months previously. There had been rapid mental deterioration for four months. Two hundred and forty cubic centimeters of air was injected. Clinically the patient was suspected of having brain atrophy, and the appearance of the ventricles on the second day corresponded with the clinical picture.

injury and encephalography, which varied from case to case, was over five months in approximately two thirds of the cases.

Methods of Examination

The patient was usually prepared with 10 mg of morphine and 0.4 mg of scopolamine. The examination itself was performed under Pentothal anesthesia,

replaced by the same amount of air. This procedure was repeated until a dry tap was obtained. The total amount of fluid removed varied, of course, from case to case. Its importance in relation to the second-day enlargement of the ventricles is discussed below.

Routine roentgenologic examination was done with the patient in the horizontal position and the

entral ray in the vertical position. Anteroposterior, posteroanterior and lateral stereoscopic views represented the routine examination, additional films were taken in individual cases. The tube-film distance was held constantly at 90 cm, the projection in various positions was standardized as much as

cedures. On the basis of past experience, the size was first judged without measurement. The ventricles were classified as normal, moderately enlarged and enlarged and were then measured. Whenever possible, the following separate measurements were made on the anteroposterior projection with

FIGURE 3 Case 1.

These films are first-day (upper) and second-day (lower) posteroanterior views.

possible. The first examination was made in the early hours of the afternoon. The second-day examination was usually done sometime during the forenoon, so that the actual time elapsed between the two examinations was between eighteen and twenty-two hours.

Various methods of measuring ventricles have been devised.^{1, 2, 9} We used two different pro-

cedures. In the patient in the horizontal position the distance between the superior medial corner of the ventricle and the convex lateral border of the ventricular body (Fig 1a), the distance between the superior medial corner and the superolateral corner of the ventricle (Fig 1b), and the distance between the superior medial corner of the ventricle and the concave lateral wall of the anterior horns (Fig 1c)

The last line formed an angle of approximately 30° with the horizontal, it was at times difficult to measure and, if so, was quite arbitrary

Like Paul and Erickson,³ we found the first measurement to be of particular significance for the actual size of the ventricles, whereas the others were

(Fig 1a) was 1.1 cm or less as normal, 1.2 cm to 1.4 cm as usually normal, 1.5 cm as borderline, and 1.6 cm as dilated. These standards were of course somewhat arbitrary, but for comparative studies they were found to be quite satisfactory. The influence of a slight variation in projection on the size

FIGURE 4 Case 2

These films show increased ventricular enlargement two days following encephalography (no films were taken on the first day following the first examination). There was no history of injury. The patient had experienced disorientation and mental confusion for six weeks. There had been slight transient papilledema. One hundred and forty cubic centimeters of air was injected. The diagnosis was brain atrophy.

at times helpful in cases of localized loss of brain substance. The decision regarding the normal limit of the size of the ventricle is of necessity arbitrary in borderline cases, in spite of studies made in large groups of probably normal encephalograms.^{1, 8} After a time, our estimated enlargement and that shown by actual measurement coincided fairly well, although in borderline cases there were some differences. We considered a ventricle whose width

of the ventricles was checked in a number of cases. It was found to have a marked influence on the "height"¹⁰ of the ventricles but produced only negligible differences in the measurements used.

RESULTS

Size of Ventricles

Of the 60 cases in which comparative second-day measurements were possible, the ventricles were

found to be larger on the second day in 23 (38 per cent). The enlargement was usually seen in the anteroposterior, posteroanterior and lateral projections but it was most easily recognizable in the anteroposterior projection (Figs 2, 3, 4, 5 and 6). In 18 cases, the second-day enlargement was con-

group of cases showed some enlargement of the ventricles on the second day, whereas approximately 8 per cent of the total group showed marked enlargement. Of 43 patients who had suffered closed or open head injuries, 18 showed some enlargement. All the cases with pronounced second-day enlarge-

FIGURE 5 Case 3

These films, which are anteroposterior views, show obvious second-day increase in ventricular enlargement. The patient had been struck on the head by a baseball six years before and was unconscious for eight days. He had had generalized convulsions for the previous five years. Neurologic examination was negative. Two hundred and ten cubic centimeters of air was injected.

sidered to be slight, whereas in 5 a marked increase in the size of the ventricles occurred in the twenty-four-hour period. A slight decrease was seen in 3 cases. In 12 cases, there was no appreciable change in the size of the ventricles on the second day, and in 22 the amount of air in the ventricles on the second day was not sufficient for measurement. In other words, slightly more than a third of the total

ment fell into the group with head injuries. In brief, of the patients with head injuries approximately 42 per cent showed some second-day enlargement of the ventricles and in 12 per cent of these the enlargement was marked.

It is interesting to compare our findings with those of Paul and Erickson.² Our technic was slightly different from theirs, inasmuch as our studies

were made with the patient in a horizontal and not in a vertical position. Only a few of our cases showed any reduction in the size of the ventricles, and the degree of decrease was not striking. It is likely that in many of our cases in which measurement in the horizontal position was not possible on the second day the ventricles would have been decreased in the upright position. The smaller percentage of

encephalographic material. Our impression is that its incidence will be fairly high in any group of cases with cerebral atrophy.

Information about the amount of spinal fluid drained at the time of encephalography was available in 36 cases of the group. In 26 cases, less than 150 cc had been drained. Second-day enlargement was slight in 6 and marked in 3. Of 10 cases in which

FIGURE 6 Case 3
These films are left lateral views on the first and the second day

second-day enlargement noticed in the material presented by Paul and Erickson³ may be partially attributed to the difference in the position of the patient, but was more probably due to the fact that only 18 per cent of their cases were post-traumatic, as compared with 71 per cent in our series. In this connection, it is noteworthy that of the 7 cases in which Paul and Erickson found second-day enlargement, there had been trauma in 4. Thus, second-day enlargement is obviously more frequent in post-traumatic patients than in the routine average

more than 150 cc had been drained, 4 patients showed slight and 2 marked second-day enlargement. In other words, the incidence of second-day enlargement was slightly higher if more than 150 cc of cerebrospinal fluid had been obtained.

In addition to the striking increase in the size of the ventricles, abnormalities observed in some of the cases made the second-day study worthwhile. The importance of the demonstration of porencephalic cysts has been emphasized by Pendergrass and Hodes,⁴ as well as by Paul and Erickson.³ In 3

of our cases the cyst was visible only on the follow-up film, whereas in 4 others the cyst, although visible at the original examination, was better filled on the second-day examination (Figs 7 and 8). In addition to the better demonstration of porencephalic cysts, second-day examination is considered

in the appearance of the septum is difficult to explain. At times it was purely an optical phenomenon, since different parts of the wavy septum were demonstrated on different days of the examination. At other times, however, the septum actually seemed to bulge markedly on the second

FIGURE 7 Case 4

The lower film, taken six days after the first examination, shows filling of a porencephalic cyst (no intermediate examinations were made). Note the defect of the frontal bone and the displaced bone fragments deep inside the vault. The patient had had a right frontal injury by a shell fragment two months previously, with immediate débridement. There was loss of memory and poor cerebrations. One hundred and forty cubic centimeters of air was injected.

of value in cases in which only one ventricle was filled on the first day and in which, by proper positioning of the head, filling of the other ventricle was obtained on the second-day examination.^{3,4}

In 8 of our cases a bulging of the interventricular septum was noted on the second-day roentgenograms (Fig 9). This was either not present or much less pronounced on the original films. The change

day, whereas it had been absolutely straight on the first day. It is likely that this is evidence of a change in the shape of the ventricles from day to day, the ventricles being not so fixed in size and shape as they are usually assumed to be. Septal bulging was found only in patients with dilated ventricles, and it is likely that the shape of the ventricles is particularly variable in patients with brain atrophy. In

7 cases the septum bulged toward the right side. There was no obvious relation between the side of maximum brain loss and the direction of the bulge.

DISCUSSION

The increase in the size of the ventricles in some of our cases was quite unexpected. Although the

follow-up examination, this was not always accomplished. A slight change in projection, however, caused no appreciable enlargement of the width of the ventricles, as we proved in especially conducted studies. In addition, a definite increase in the size of the ventricles on the second-day examination was found in cases in which the projections on the two

FIGURE 8 Case 5

The lower film demonstrates second-day filling of a porencephalic cyst. Note the air-filled cyst above the dilated anterior horn. The patient had had a left frontoparietal injury due to grenade fragments and followed by debridement. There had been marked aphasia, which had improved. There was an old papilledema, with diminished vision, as well as slight headache and dizziness. The brain protruded through the skull defect, and most of the porencephalic cyst was within the protrusion. One hundred and eighty cubic centimeters of air was injected.

observation appears to be irrefutable, the explanation is difficult and debatable. An explanation on a purely optical basis can be excluded. The various examinations were performed under identical circumstances, and the same optical conditions existed. The size of the frontal sinuses was measured routinely and was found to be identical in the different examinations of a given case. Although an attempt was made to reproduce the original projection in the

examinations were identical. In short, there can be no doubt that the ventricles in these cases were larger on the second day.

The question arises regarding the correct size of the ventricles in such cases. Were the ventricles on the first-day examination smaller than they normally are, or was there a transient abnormal increase in their size on the day following the introduction of air? Paul and Erickson² apparently as-

sume that the second-day dilatation is the artificial finding and give the following possible explanations: Gas, trapped at the base of the skull — in the cervical region, the cisterna magna or the subarachnoid space of the posterior fossa or even in the third or fourth ventricle — passed upward. This explanation appeared to be applicable to some of our cases. Rapidly emptying gas from the subarachnoidal space

that the brain responds rapidly to decreased intracranial pressure by an increase in volume. Such increase may be due to either edema or hyperemia of the brain. One may assume that the sudden withdrawal of all the ventricular fluid represents a marked trauma to the brain which quickly responds to such trauma. In other words, the enlarged brain presses from all sides on the ventricles and de-

FIGURE 9 Case 6

The lower film shows the second-day bulge of the septum pellucidum. The patient had had grand-mal attacks for four years, but there was no history of trauma.

caused dilatation of the ventricles. An abnormality was present in the gaseous interchange between the air in the ventricles and the gases in the cerebral tissues or blood vessels. Finally, a difference in the intracranial pressure for the two days or, to a lesser extent, in the temperature altered the gas volume.

In our opinion, it is difficult to say whether the size on the first or the second day represents the normal condition of the ventricles. It is well known

increases their size. Within twenty-four hours the irritation caused by the sudden withdrawal of fluid subsides and the ventricles resume their normal size. In favor of this assumption is the fact that in patients in whom films were taken after twenty-four hours, no further increase in the size of the ventricles was noted. This theory also explains why, in a few cases of severe, repeated brain trauma with clinical signs of considerable brain damage, the ventricles

7 cases the septum bulged toward the right side. There was no obvious relation between the side of maximum brain loss and the direction of the bulge.

ARTHRITIS IN THE MEDITERRANEAN THEATER OF OPERATIONS*

II. Clinical Description of Hypertrophic Arthritis, Arthralgia and Psychogenic Rheumatism

LIEUTENANT COLONEL CHARLES L. SHORT, MC, AUS

THE types of joint disease often encountered in the Mediterranean Theater, in addition to rheumatoid arthritis, which was discussed in a previous paper,¹ included hypertrophic arthritis, arthralgia and similar disorders, and psychogenic rheumatism

HYPERTROPHIC ARTHRITIS

The aspects of hypertrophic arthritis that seemed of importance in the Theater are covered in this section, no attempt being made to discuss the definitive treatment of the disease. Because it was usually employed, the designation "hypertrophic arthritis" is used throughout to avoid confusion, although in some ways its synonyms, such as "degenerative joint disease" and "osteoarthritis," are preferable. When possible, the two types of hypertrophic arthritis encountered in military as well as in civilian practice are differentiated and compared. These are the primary usually more generalized type and the secondary more localized type, resulting from structural abnormality, previous trauma or joint damage caused by another form of arthritis.

Incidence

The exact incidence of hypertrophic arthritis in the Theater could not be determined. A total of 621 cases were reported by questionnaires from ten general hospitals. This figure may be somewhat higher than the actual one because of both duplication of cases and a tendency to diagnose the disease from x-ray findings when it might not be responsible for the patient's disability. Hypertrophic arthritis made up about 25 per cent of the total number of patients with arthritis admitted to general hospitals, a ratio approximating that found by Boland and Corr² in a general hospital in the United States. The prevalence of this disease, which is generally regarded as an affection of middle or old age, in an overseas theater seems unusual until the large number of soldiers in their late thirties are taken into account as well as the still older commissioned and noncommissioned officers of the higher grades. In addition, the secondary type, which is usually symptomatic at an earlier age, made up over a third of the cases diagnosed as hypertrophic arthritis.

Etiology

Table 1 presents the age distribution of 51 cases of hypertrophic arthritis, with a comparison between primary and secondary types. The mean age of the primary type, forty-one years and eight months, sur-

passed by about ten years that found for a series of patients with rheumatoid arthritis.¹ In spite of the small number of cases, a significant difference also seemed to exist between the two forms of hypertrophic arthritis, since the majority of cases in the primary type occurred in the fifth decade of life in comparison with the fourth decade in most of the other group.

The cause of the primary type of hypertrophic arthritis remains unknown, although aging and degeneration of articular cartilage certainly constitute the underlying process. Other etiologic factors are therefore difficult to assess, although exposure to cold and dampness, sleeping on the ground and the strain of long marches, especially in mountainous country, and of riding in army vehicles were all cited by patients as precipitating causes of disabling symptoms. Acute trauma to a joint in the form of a strain or a direct blow from a fall also preceded the onset in certain cases or caused an acute exacerbation in a previously mild process. All these factors were also operative in bringing patients with the secondary type to medical attention, although the underlying process was usually initiated years previously. Table 2 lists a classification of the factors apparently causing or accelerating the development of the secondary type of hypertrophic arthritis. These data were derived from the records of 100 such patients in a combined series of 270 cases in which the diagnosis was made. A study of the table reveals that trauma was a cause about three times as frequently as a long-standing or congenital structural abnormality. The types of trauma were about equally divided between an actual fracture, either ununited or healing in a position to throw strain on one or more joints and direct or indirect trauma to the joint itself. One patient developed hypertrophic arthritis of the shoulder joint secondary to the continued presence in the joint of shot-gun pellets, acquired four years previously. This case, together with others previously reported, points to the importance of the removal of missiles or shell fragments from joints to prevent what has been called "foreign-body arthritis."

Diagnosis and Clinical Features

From the data given above regarding age incidence and from the general experience in the Theater, hypertrophic arthritis was naturally suspected when an older patient presented himself with joint complaints. A previous history of similar symptoms, usually low-grade, was frequently obtained especially in response to unfavorable climatic conditions or unusual exertion. In many cases there

*The following material represents a condensation and a certain amount of revision of parts of a clinical monograph on arthritis prepared at the direction of the Surgeon, Mediterranean Theater of Operations, United States Army and submitted to him in final form in June 1945.

appeared normal, or almost normal, on the first day and showed dilatation on the second day. This second-day dilatation of the ventricles coincided better with what had been expected from the clinical picture.

On the other hand, it is conceivable that the first-day examination represented the normal size of the ventricles and that the irritation of the air in the ventricles caused hypersecretion to such a degree that it was inadequately drained through the foramina of the fourth ventricle and thus led to dilatation of the ventricles. In favor of this theory, is the fact that the second-day enlargement was generally seen if large amounts of air had been introduced. The evidence against this theory, however, is stronger than that in favor of it. In some cases the ventricles not only were larger on the second day but also contained more air than on the first day. Hypersecretion, with an increase of the pressure within the ventricles, should press the air out into the subarachnoid space and should not attract it.

Measurements of the cerebrospinal-fluid pressure at the time of introduction of air and again on the day following the encephalography would be interesting. The latter measurements were not made in this series.

Although a satisfactory explanation of second-day enlargement is not possible, we are inclined to believe that if the ventricles enlarge within twenty-four hours, the second-day examination represents the normal or resting size. Further clinical and experimental studies regarding this problem appear to be necessary.

There are certain practical applications of the recognition of this phenomenon. We have not seen pronounced second-day enlargement in cases without fairly marked clinical evidence of brain damage. For this reason, routine study of the ventricles twenty-four hours after the introduction of air is advised. This study is particularly indicated in cases with old head injuries or in those in which atrophy from other causes is suspected. The second-day examination not only often shows bilateral or unilateral dilatation that was not present on the first day but also, at times, emphasizes and clarifies certain anomalies that were equivocal on the first

day. We have seen a few cases in which the second day examination clearly showed the presence of brain atrophy, whereas that on the first day had left the question of tumor or atrophy open.

SUMMARY

Observations in 60 patients who had roentgenologic studies on the day following routine encephalography are described. Thirty-five of these had open and 8 had closed injuries, 7 were epileptic, and in 10 the examination was performed for other reasons.

A slight decrease in the size of the lateral ventricles on the second day was seen in 3 cases. The lateral ventricles were slightly larger on the second day in 18 cases, and there was marked enlargement in 5 cases. Each of the last cases had a history of preceding head injury.

At times, a peculiar bulging of the interventricular septum was seen on the second day. Second-day studies showed filling of porencephalic cysts that were not filled, or incompletely filled, on the first day.

The mechanism of second-day enlargement is discussed.

Roentgenologic studies on the day following encephalography appear to be indicated, particularly when the examination is performed for the diagnosis of post-traumatic conditions.

ted by orthopedic measures, chiefly exercises to improve bodily mechanics and strengthen supporting muscles with the occasional use of foot plates or supports for the lower back. Except in severe cases, a trial of such methods seemed justified with a view to returning the patient to some form of duty, usually at a lower level of physical activity than in his previous assignment. In planning the extent of the treatment and hospitalization, it was of assistance to realize that the disease is prone to partial or even nearly complete symptomatic remissions both spontaneous and in response to the removal of environmental or occupational factors causing excessive strain on the affected joints. Each case was necessarily handled individually, with the knowledge that the severity of the arthritis as evidenced by the x-ray film, did not necessarily foretell the outcome.

Disposition

Combined figures for the disposition of 621 patients with hypertrophic arthritis obtained from ten general hospitals were as follows: to duty, 66 (10.6 per cent), to limited service, 170 (27.4 per cent), and for evacuation, 385 (62.0 per cent). In addition, the probability exists that in many diagnosed as hypertrophic arthritis in station and evacuation hospitals and in the Third Convalescent Hospital the patients were returned to some form of duty without having reached a general hospital.

The disposition in each case was often unpredictable when the patient was first admitted. Cases in which the indications for evacuation were clear from the start included severe cases of the primary type and those with the secondary type in which the underlying cause made improvement under ordinary measures unlikely, as well as patients who had been tried unsuccessfully at limited service and those whose symptoms failed to improve sufficiently with previous hospitalization. It seemed fully justifiable to classify the remainder for limited service with the expectation that, in the majority, the symptoms would be sufficiently controlled to enable the patients to be of use in an assignment in the Zone of Communications not involving undue strain on the involved joints. A small remainder, with mild symptoms responding readily to treatment or with light assignments, were sent to full duty. Finally, the impression was gained that a smaller number of patients were evacuated in the Italian than in the North African phase of operations.

ARTHRALGIA, MYOSITIS AND MYALGIA

This group might be called the "unwanted stepchild" of the arthritic diseases as seen in the Theater. The patients presented complaints without objective findings, were often suspected of neurosis or malingering and furnished real difficulty in diagnosis, treatment and disposition. But, since the cases made up the largest proportion with com-

plaints referable to the joints and other supporting structures, the condition had to be dealt with if not always to the satisfaction of the medical officer's scientific principles, at least in a practical manner. In the collection of data, even more than the usual confusion associated with the nomenclature of the arthritic diseases was encountered. The most frequent term employed in the diagnosis of patients with pain and stiffness of the joints without evidence of a real arthritis or an underlying neurosis was "arthralgia." Myositis or myalgia was employed

when the symptoms were localized to the region of muscles rather than joints and when the process was relatively acute. A few hospitals used "fibrositis" or the variation "fibromyositis," according to British usage, which is followed by some in the United States under the assumption that a definite pathologic process is responsible — namely, inflammation of white fibrous tissue. Since this assumption has never been adequately proved, it seemed preferable to discard the term "fibrositis" for the present purpose. Furthermore, since a definite myositis is as incapable of proof as fibrositis in most cases and since, in many cases, the symptoms were in the region of both joints and muscles it was decided to utilize in this section the terms "arthralgia" and "arthralgia group." In this way, unwarranted implications concerning pathology and pathogenesis were avoided, as well as those regard-

had been remissions, either spontaneous or in response to rest or hospitalization. In the secondary type, as might have been expected, the underlying cause was usually operative and productive of some symptoms before entrance on active duty.

In common with civilian experience, objective joint changes were less striking in hypertrophic than in rheumatoid arthritis, acute synovitis or effusion being rare and usually occurring in response to superimposed recent trauma. Findings were limited

diagnosis. In fact, medical officers without exception stated that a definite diagnosis of hypertrophic arthritis was not made in the absence of x-ray changes. As pointed out below under arthralgia, however, the presence of an early hypertrophic arthritis without x-ray changes may have been surmised but not diagnosed in certain patients on account of their age and the localization of symptoms.

Since the diagnosis of hypertrophic arthritis depended almost entirely on positive x-ray findings,

largely to crepitus, tenderness, bony irregularity and slight degrees of limitation of motion. The distribution of the arthritis was of some assistance in diagnosis and corresponded to that noted in civilian life. In the 33 patients with the primary type listed in Table 1, the upper extremities, including the shoulders, fingers and acromioclavicular joints, were rarely the seat of symptoms. Heberden's nodes, except for the form secondary to athletic or occupational trauma, were seldom noted in soldiers in the Theater. The spine was oftenest involved, chiefly in the lumbar region, although radicular pain associated with hypertrophic arthritis of the cervical spine was occasionally recorded. Next to the spine, joints of the lower extremities were most frequently affected, especially the hips and knees. In one hospital, a number of patients with hypertrophic changes in the tarsal joints had been admitted with a diagnosis of foot strain.

In the primary type of hypertrophic arthritis, bilateral involvement of corresponding joints was present in a fair number of cases, but a symmetrical distribution was nowhere near so striking as in rheumatoid arthritis. Bilateral arthritis was unusual in the secondary form, in which there was a wider distribution of articular involvement (Table 2) and in which the spine, knees and hips were generally involved.

Laboratory tests were of little assistance in the diagnosis of either type of hypertrophic arthritis. The sedimentation rate was usually normal. Roentgenograms, on the other hand, were essential in the

there is little need of discussing the differential diagnosis. The danger of assuming that the patient's symptoms were necessarily associated with these findings was apparent, however, especially in dealing with radicular pain, in which the ruling out of other possible causes was rightly considered a prerequisite to a final diagnosis of hypertrophic arthritis alone. In a certain number of cases the symptoms were chiefly or entirely dependent on neurosis rather than the arthritis demonstrated by x-ray examination. The finding of mild degrees of hypertrophic arthritis in older soldiers, who may have had skeletal symptoms but whose chief trouble was a lack of sufficient stamina for combat duty, led to the use of this diagnosis as a convenient method of assigning the patients to limited service. Among 132 patients sent to limited service with a diagnosis of arthritis by the Third Convalescent Hospital, a report states that 20 should more properly have been designated "over age for combat service."

Treatment and Course

Since articular cartilage is a tissue displaying little capacity for repair, the changes in hypertrophic arthritis are irreversible, and the condition is usually slowly progressive. No specific medical treatment is available, and surgery to correct causative or accelerating factors was rarely indicated in an overseas theater. The measures employed were therefore chiefly symptomatic and consisted largely in rest and freedom from weight bearing, as well as in the application of heat. Certain cases were bene-

ted by orthopedic measures, chiefly exercises to improve bodily mechanics and strengthen supporting muscles with the occasional use of foot plates or supports for the lower back. Except in severe cases, trial of such methods seemed justified with a view to returning the patient to some form of duty, usually at a lower level of physical activity than in his previous assignment. In planning the extent of the treatment and hospitalization, it was of assistance to realize that the disease is prone to partial or even nearly complete symptomatic remissions both spontaneous and in response to the removal of environmental or occupational factors causing excessive strain on the affected joints. Each case was necessarily handled individually, with the knowledge that the severity of the arthritis, as evidenced by the x-ray film, did not necessarily foretell the outcome.

when the symptoms were localized to the region of muscles rather than joints and when the process was relatively acute. A few hospitals used "fibrositis" or the variation "fibromyositis," according to British usage, which is followed by some in the United States under the assumption that a definite pathologic process is responsible — namely, inflammation of white fibrous tissue. Since this assumption has never been adequately proved, it seemed preferable to discard the term "fibrositis" for the present purpose. Furthermore, since a definite myositis is as incapable of proof as fibrositis in most cases and since, in many cases the symptoms were in the region of both joints and muscles it was decided to utilize in this section the terms "arthralgia" and "arthralgia group." In this way, unwarranted implications concerning pathology and pathogenesis were avoided, as well as those regard-

ing the presence of a chronic or progressive disease. The objections noted above apply also to the use of the diagnosis "chronic arthritis, type undetermined," as employed in some hospital records. Since no attempt was made to cover the subject of organic or functional disorders of the lower back, unless caused by some form of arthritis, patients with pain and stiffness confined to this region were not included under the heading of arthralgia. More definite and localized affections are also not considered, such as strains, sprains, bursitis and tenosynovitis.

Incidence

No exact figure can be given for the incidence of arthralgia in the Theater. A total of 918 cases were reported by questionnaire from ten general hospitals, 497 being labeled arthralgia and 421 myositis or myalgia. This figure probably needs little correction for duplication of cases and, in fact, should be higher, with the addition of patients from the group with the diagnosis of chronic arthritis, type unspecified. The patients with arthralgia probably made up nearly 40 per cent of the total number with arthritis admitted to general hospitals, as compared with about 25 per cent each for rheumatoid and hypertrophic arthritis and 10 per cent or less for specific infectious arthritis. The incidence of arthralgia was probably higher in lower medical echelons in the Theater, since many patients were undoubtedly discharged to duty without having been admitted to a general hospital. Patients without objective findings of joint disease were reported to make up the majority of those admitted with articular complaints to one evacuation hospital, whereas they comprised at least half of those listed under arthritis in the records of the Seventy-third Station Hospital. Other available figures in World War II include an incidence of 70 per cent for "fibrositis" among the patients with arthritis admitted to two British general hospitals in 1940,³ contrasted with 5 per cent in a general hospital in the United States² and 13.6 per cent at the Army and Navy General Hospital, Hot Springs, Arkansas.⁴ The smallness of the last percentages may have been due to the fact that in the American hospitals a special search was made for cases of psychogenic rheumatism among the patients without evidence of real arthritis. In World War I, in about 25 per cent of the 65,192 patients admitted to Army hospitals for arthritis the diagnosis was muscular rheumatism or myositis.⁵

Etiology

A sample to show the age distribution of patients with arthralgia was obtained from a series of 86 patients in the records of the Medical Service of the Twelfth General Hospital (Table 1). Patients were selected, irrespective of the hospital diagnoses, who complained of pain and stiffness in and around the joints without clinical, laboratory or x-ray evidence

of arthritis. This group tended to be made up of older patients, the mean age (thirty-four years and one month) being higher than that in rheumatoid arthritis (thirty years and nine months), but considerably lower than that in hypertrophic arthritis (forty-one years and eight months). This finding, although noted in other hospitals, may be only apparent, since a frequent practice in the Theater was to return young patients with arthralgia to duty, whereas older soldiers were likelier to be sent to a general hospital to be classified for limited service. No clue was obtained in the Theater regarding the actual causes of arthralgia, but precipitating factors included severe exertion and exposure to cold and dampness. An increase in the number of cases from the Fifth Army hospitals was noted at the Third Convalescent Hospital at the beginning of the cold and rainy season. There were few cases of acute infections of the upper respiratory or gastrointestinal tract directly preceding the onset of symptoms, although such conditions were often accompanied by transitory skeletal aches and pains.

Diagnosis and Clinical Features

In the diagnosis of arthralgia, a careful history was all important. Unless the patient's symptoms were characteristically "rheumatic," a strong suspicion of psychogenic rheumatism properly arose. The necessary points for a rheumatic symptomatology may be listed as follows: morning stiffness and an increase in pain after sitting or lying in one position during the day, aggravation by cold, dampness or weather changes, and at least temporary relief from heat, moderate exercises and aspirin. Severe exertion, with overuse of the joints and muscles during the day, may, of course, cause an increase in pain or stiffness toward evening as well as on arising. It was found necessary for the examiner to avoid the use of leading questions and to realize that a soldier may have had an opportunity to compare notes with a fellow sufferer from arthritis, especially on a hospital ward. Marked constitutional or vasomotor symptoms were unusual in this group and, when present, suggested the possibility of a mild rheumatoid arthritis. The same observation held true of neurologic symptoms, with motor weakness and tremor again suggesting rheumatoid arthritis. Bizarre paresthesias or numbness in contrast to genuine pain and stiffness were often indicative of a psychogenic origin of symptoms.

The physical examination in these patients showed no objective changes in the form of swelling or joint effusion, although the patient might complain that his joints felt swollen. Mild or moderate degrees of limitation of motion, which were occasionally present, were associated with muscle spasm or stiffness rather than actual loss of joint function. Tenderness over joints, muscles and other supporting structures and pain on motion of joints or on stretching of muscles were frequently elicited. The

distribution of involvement is presented in Table 3. As indicated by the figures, many patients had involvement of multiple regions, the lower extremities being affected about twice as often as either the back or the upper extremities.

The sedimentation rate was uniformly normal in patients with arthralgia. The one exception consisted in a few patients with marked tenderness chiefly localized to the lumbar paravertebral muscles, in all of whom the sedimentation rate was moderately elevated, and in some cases there was a suggestion of muscle swelling, along with fever and leukocytosis. The course was that of slow improvement, with a disappearance of symptoms and signs and a return to normal of laboratory findings. Despite careful observation over a relatively long period, they never developed evidence of disease of bones or joints and were eventually returned to duty. In such patients alone, a diagnosis of myositis seemed justified. X-ray examination of the involved region was performed in nearly all hospitalized patients with arthralgia, with negative results.

Differential Diagnosis

A final diagnosis of arthralgia in a patient with the findings described above depended on the exclusion of either a real arthritis or an underlying neurosis as a cause for symptoms. Much difficulty arose in the elimination of an early, mild rheumatoid arthritis, since the articular distribution including symmetry often suggested this disease. The differentiation of hypertrophic arthritis depended almost entirely on the x-ray findings. In many patients, on account of the age distribution (Table 1) and the localization of symptoms to the back and lower extremities (Table 3), the question of an early hypertrophic arthritis without x-ray changes was properly raised. In such cases the practice was to employ arthralgia as an immediate diagnosis, with the reservation that hypertrophic arthritis might be revealed by x-ray study at a later date. A careful orthopedic check-up examination proved useful in a number of patients by revealing structural abnormalities that might previously have been overlooked. These included foot strain, genu valgum, varum or recurvatum, bursitis in various localities and organic changes of the spine. Rheumatic fever was rarely difficult to distinguish, but electrocardiographic study of an occasional case showed a definite increase in the PR interval and favored a presumptive diagnosis of this disease.

Most important of all to eliminate in the arthralgia group was a neurotic basis for symptoms, or so-called "psychogenic rheumatism." The distinction was made on two grounds: the demonstration of an underlying neurosis, with psychiatric aid in certain cases, and the finding, after careful evaluation, that the patient's symptoms were not characteristically "rheumatic," as described above. In certain patients, in whom both neurosis and arthralgia were

apparently present, careful clinical judgment was required to ascertain the predominant factor, the use of two diagnoses occasionally being justified. The medical officer was helped in this decision by the age of the patient (the symptoms seemed genuine more frequently in older patients) and, if available, by the opinion of the soldier's commanding officer. It seemed probable, however, that many cases of neurosis had inaccurately been labeled arthralgia or a similar diagnosis. The much larger number of patients found in a general hospital in the United States with psychogenic rheumatism than fibrositis has been mentioned above,² whereas in civilian prac-

TABLE 3 Areas of Body Affected by Arthralgia among 86 Patients, as Obtained from the Records of the Twelfth General Hospital

tice in England, Halliday⁶ considered the disability due to psychogenic factors in 37 per cent of 62 insured patients with a diagnosis of rheumatism. The question of malingering occasionally arose in these patients but seemed incapable of proof. Conscious or unconscious exaggeration of symptoms was not unusual, however, and was generally readily recognized and appropriately handled by the medical officer.

Treatment and Course

The treatment of the patients with arthralgia was usually symptomatic and included the benefits of hospital shelter and care (rest, warmth, sleeping off the ground and avoidance of severe exertion), relief of pain with salicylates and physical therapy in the form of heat, massage and exercises. Some success was attained in the more acute, localized types, but the generalized forms seemed to derive only temporary, if any, alleviation of symptoms. In the latter, prolonged hospitalization proved ineffective and indeed wasteful of bed space and manpower once the diagnosis had been established. A decision regarding diagnosis and disposition was therefore indicated as quickly as possible. Along these lines, greater stress should have been laid on handling the problem more frequently in the Army area or in station hospitals in the Zone of Communications. In this way, with a relatively short period of observation, a sorting could have been made of cases

that were obviously functional, those with arthralgia and those with probably real arthritis. Fewer patients in the first two groups would then have needed to be sent to general hospitals.

Disposition

Figures from ten general hospitals showed the following proportion of dispositions for 918 patients with arthralgia to duty, 538 (58.6 per cent), to limited service, 263 (28.6 per cent), and for evacuation, 117 (13.8 per cent). The percentage of patients with myalgia or myositis who were evacuated was essentially the same as that in cases of arthralgia, but a greater proportion of the former were returned to full duty. It was the opinion of medical officers questioned in evacuation and station and most general hospitals that a large majority of the patients with arthralgia were sent to duty. The exceptions comprised patients who had repeatedly failed at full duty, older soldiers who were otherwise unsuited for combat and those whose commanding officers believed that they should be reclassified. The small number evacuated were mainly soldiers who were unable to perform even limited service or those with a severe psychoneurosis in addition. The remainder were sent to limited service and were usually able to carry on without rehospitalization. In summary, from the general hospital figures, nearly 90 per cent of patients with arthralgia were returned to some form of duty, with the probability that an even larger proportion from evacuation and station hospitals were sent to full duty, rather than to limited service.

PSYCHOGENIC RHEUMATISM

The term "psychogenic rheumatism" was adapted from the work of Boland and Corr² at the Hoff General Hospital, Santa Barbara, California. Their definition of this condition is as follows: "states in which symptoms such as pain, stiffness, subjective sense of swelling or limitation of motion in the muscles or joints are caused, intensified or perpetuated by mental influences." A similar name, "psychosomatic rheumatism," was used in England for a number of years by Halliday,⁷ who stressed the high incidence of this cause of articular symptoms, especially in cases labeled fibrositis. Although psychogenic rheumatism is a convenient and concise descriptive term for this group of patients, it should be made clear that it is not advocated as a final diagnosis in the records of Army or civilian hospitals. The usual diagnoses of neurosis or psychoneurosis, with the type and manifestations, should be employed.

Incidence

About one sixth (16.5 per cent) of 309 patients with articular complaints admitted to the Medical Service of the Twelfth General Hospital were believed to be suffering from psychogenic rheumatism.

This proportion, which was equaled by that of patients with hypertrophic arthritis and was exceeded by patients with arthralgia (33.4 per cent) and rheumatoid arthritis (24.8 per cent), outnumbered the remainder, chiefly patients with specific infectious arthritis (8.0 per cent). At the Army and Navy General Hospital, in 18.8 per cent of patients with rheumatic complaints the diagnosis was psychogenic rheumatism,⁴ a somewhat greater proportion—60 (26 per cent) of 231 patients with peripheral joint involvement—being so classified by Boland and Corr,² who were especially interested in and on the lookout for this condition. These authors, in fact, found psychogenic rheumatism the most frequent cause of disability encountered in their series, although the incidence was only slightly in excess of that of rheumatoid arthritis.

Another method of approach to the incidence of psychogenic rheumatism was an estimate of the proportion of cases of neurosis manifested by symptoms referred to the joints, muscles or other supporting structures. In a study of patients admitted to the Fifty-sixth Evacuation Hospital with diagnoses of organic diseases, 174 patients whose symptoms were actually on a functional basis were recorded and classified. The diagnosis of some form of arthritis on admission was made in only 13 (7.5 per cent), as compared with 51 patients, or 29 per cent, admitted with gastrointestinal disease, 25 patients, or 14 per cent, with upper respiratory symptoms, 19 patients, or 11 per cent, with backache and 14 patients, or 8 per cent, with headache. These figures were also confirmed by neuropsychiatric opinion, which put articular manifestations of the neuroses at the end of a list including, in order of frequency, backache, gastrointestinal symptoms, headache and cardiovascular symptoms. At the Six Hundred and First Clearing Company, where patients with neuroses were gathered directly from the Fifth Army and were nearly all considered "battle incurred," this symptom-complex was rarely encountered. Most of the patients manifested "free anxiety," and it was believed that somatic symptoms in this group usually developed after hospitalization. Major hysteria, however, in the form of gaits, postures and joint symptoms that might mimic a real arthritis, made up perhaps 2 or 3 per cent of the admissions. A few such patients were also seen in hospitals in the Zone of Communications, only 10 being listed in the questionnaires. The experience of Boland and Corr² in the United States is at variance with the information available for the Mediterranean Theater. These authors stated that disabling psychogenic complaints, as observed in an Army general hospital, were displayed frequently in the joints and muscles and were comparable to their occurrence in the gastrointestinal and cardiovascular systems. The difference may lie in the as-siduity with which they searched for this type of

case and in the fact that they included patients with low-back symptoms on a functional basis

Etiology

The immediate precipitating emotional cause, as Boland and Corr² have pointed out, was difficult to elicit and was not often found in the records. Factors common to the development of other manifestations of neurosis in troops overseas were undoubtedly active and need not be listed here. In general, the patients seemed younger than those with an actual arthritis and, as one medical officer put it, "can be picked out of the younger patients with arthralgia." Table 1 shows the age distribution in 51 patients from the records of the Twelfth General Hospital. A comparison with other types of arthritis in this table reveals that patients with psychogenic rheumatism approximately equaled in age those with rheumatoid arthritis, but comprised a definitely younger group than those with hypertrophic arthritis or arthralgia. In Boland and Corr's² series, on the contrary, no relation to age was found.

Except in the experience of the Six Hundred and First Clearing Company, precipitation or aggravation by combat was frequent, about half the patients admitted to the Twelfth General Hospital having given this history. A distinction was not always made in the record, however, between the onset of the anxiety state and the actual somatic fixation. In common with the findings of Boland and Corr,² about half the patients presented a history of articular symptoms. In many of these cases there was an actual history of injury to a joint or a preceding disease accompanied by pains in the joints, such as rheumatic fever, influenza or meningitis (stiff neck), but without objective changes on examination. In most cases it was impossible to determine from the record whether the patient had had psychogenic rheumatism in the past or whether the previous injury or disease had merely provided a site for somatic fixation of the neurosis. A family history of "rheumatism," found in over a third of the patients studied in the United States, was not prominent in the Theater, except for a few striking cases, but might have been brought to light oftener by direct questioning. The presence of an underlying neurosis, dating back to civilian life in over half the cases, evidently furnished the cause for the development of somatic symptoms. This was brought out by past and family histories of neuropathy and by the elicitation of other psychosomatic symptoms, some on a frankly hysterical basis. About half the patients at the Twelfth General Hospital gave evidence of general or localized functional symptoms in addition to those directed toward the joints. The role of hospitalization in the development of somatic symptoms, as postulated by the Six Hundred and First Clearing Company, was difficult to demonstrate with numerical data, but most medical officers questioned could recall specific cases, occasionally

with direct contagion from fellow patients with joint complaints

Diagnosis and Clinical Features

The diagnosis of psychogenic rheumatism depended on two criteria. The first was the ruling out of organic disease as the important factor in the patient's complaints, with the aid of the principles outlined in the sections on individual types of arthritis and, in doubtful cases, with the help of a careful orthopedic examination. The second consisted in the establishment of a positive diagnosis of neurosis, by a family or past history of neuropathy and by the presence of other psychosomatic symptoms. Persistence or return of symptoms localized to the site of previous disease or injury was useful in arousing suspicion, as well as a family history of joint disease with symptoms similar to those of the patient. Bizarre complaints, including paresthesias and numbness and symptoms not typically "rheumatic" (as outlined above), served to direct the examiner's attention to functional disease. In certain patients the opinion of a psychiatrist was of great value, either in confirmation of the internist's opinion or to bring out the patient's neurotic background by a trained psychiatric approach.

The physical examination in these patients was usually entirely negative. A certain number presented joint limitation or deformity associated with muscle spasm. Others showed mild residual changes that were obviously not responsible for the symptoms. In a third group, areas of hysterical anesthesia were present, either in a glove and stocking distribution or in the neighborhood of the involved joints. Patients with hysterical gaits and postures, including camptocormia, and with joint deformity without actual arthritis were usually easily identified, sometimes with the aid of sodium amytal narcosis. The distribution of articular involvement corresponded to that found by Boland and Corr,² the majority complaining of symptoms in the back and lower extremities, compared with a smaller number of cases with symptoms in the upper extremities or generalized.

The psychiatric diagnosis made in the 51 patients from the Twelfth General Hospital was variable, without the majority showing an anxiety state as found in the series in the United States.² A classification of the types of psychoneurosis is as follows: conversion symptoms or hysteria, 18; anxiety state, 18; hypochondriasis, 7; unclassified or mixed, 4; and constitutional psychopathic state, 4.

In the differential diagnosis organic types of joint disease, including arthralgia and orthopedic conditions, were chiefly considered. Rheumatoid arthritis furnished some difficulty even after a careful examination and an adequate period of observation. Several patients were seen, however, who had been admitted with a diagnosis of neurosis and whose symptoms were found to be entirely explain-

able on the basis of rheumatoid arthritis with marked constitutional manifestations. In a larger number — 10 of 132 patients at the Sixth General Hospital with rheumatoid arthritis — two diagnoses were properly made, with the coincident neurosis usually of the anxiety type. In some cases the arthritis apparently became worse after the development of the neurosis, but in at least one soldier who had carried on in spite of a well marked arthritis, the anxiety was obviously secondary to the disability and to a feeling of helplessness in the presence of danger. Since the diagnosis of hypertrophic arthritis was made largely by means of x-ray examination in the Theater, patients chiefly required mention whose symptoms were out of all proportion to the organic findings. Such patients, if there was positive evidence of neurosis, were usually given two diagnoses, one of which included "psychoneurosis, manifested by elaboration of a minor organic illness." Others, who showed hypertrophic changes only incidentally or with presenting symptoms entirely unrelated, were also given two diagnoses, with the lack of importance of the arthritis clearly indicated. Points found useful in the distinction between arthralgia and psychogenic rheumatism have been outlined above. As a final check, even in apparently clear-cut cases of neurosis, it was well to have an orthopedic examination to eliminate structural changes of the skeletal system as a partial or complete cause of the patient's disability.

Treatment and Course

The treatment of psychogenic rheumatism was largely unsuccessful once the patient reached a general hospital, whether the symptoms were long present, were precipitated by combat or the hardships of military life or became localized and fixed during previous hospitalization. About all that was accomplished was to reassure the patient (and the medical officer) that no serious form of arthritis was present and to determine the disposition according to the patient's degree of disability. An even more pessimistic conclusion was reached by Boland and Corr,² who found that their efforts to return such patients to full or limited duty were largely unsuccessful. Their group, however, was made up of men undergoing training in the United States, and in many cases the only solution was the removal of the underlying mental conflict, which could be accomplished by separation from military service. The authors stress the need for prompt recognition and proper psychotherapy instead of physical therapy, a point that was equally applicable, as mentioned above, to the Theater. For example, it was found possible at the Six Hundred and First Clearing Company to send most of the patients with hysterical manifestations localized to the skeletal system at least to limited service by early applica-

tion of treatment before the symptoms became intensified and fixed. The methods consisted in the clearing up of symptoms with the aid of barbiturate narcosis and suggestion. The patients were usually told in addition that their combat days were over but that prolonged and unpleasant hospitalization was in store for them unless they became well enough for limited service.

Disposition

In the series of 51 patients with psychogenic rheumatism from the Twelfth General Hospital only 4 (8 per cent) were returned to duty, 30 (60 per cent) were sent to limited service and 17 (32 per cent) were evacuated. Although it was agreed that disposition by general hospitals should be individualized according to the degree of neurosis and an estimate of the patient's ability to perform useful service, the impression was gained that the majority were discharged to limited service. A few, especially those with mild or exaggerated symptoms, were sent to full duty, such a disposition being more probable in forward medical echelons. The remainder, usually with a severe underlying neurosis and a deep fixation of symptoms, were evacuated.

SUMMARY

Hypertrophic arthritis was encountered in the Mediterranean Theater as frequently as rheumatoid arthritis, a finding associated with the presence of older officers and soldiers and a high incidence of the secondary type. Symptoms usually existed prior to induction, the hardships and physical strain of military service being precipitating factors in hospitalization. Previous joint trauma or fractures were responsible for the development of the secondary type about three times as often as structural abnormalities. The diagnosis of hypertrophic arthritis was established by x-ray examination, with care necessarily taken to ascertain the relation of the x-ray findings to the patient's disability. The proportion of patients sent to limited service was greater than that in patients with rheumatoid arthritis.

Reasons are advanced for the use of the term "arthralgia" in patients with symptoms referred to the joints, muscles and other supporting structures, without evidence of a true arthritis or a causative neurosis. The high incidence of cases of arthralgia is stressed. Symptomatic treatment was effective only in the acute and localized forms, in which the diagnosis of myositis or myalgia was often made. Over 50 per cent of these patients were returned to full duty, and another 25 per cent to limited service.

At least a sixth of the patients with articular complaints were found to have a neurotic basis for their symptoms — so-called "psychogenic rheuma-

tism" Articular localization of psychosomatic manifestations was less frequent than backache, headache and gastrointestinal or cardiovascular symptoms. Precipitation or aggravation of the neurosis by combat was frequent, and many patients gave a history of previous joint disease or injury. About half the patients had additional generalized or localized functional symptoms. Treatment was ineffective except in patients seen soon after the onset of symptoms in a forward area.

CLINICAL NOTE

MONGOLISM FOLLOWING INTERCURRENT INFECTIOUS DISEASE IN PREGNANCY*

THEODORE H. INGALLS, M.D.† AND
JOHN A. V. DAVIES, M.D.‡
BOSTON

IT IS generally agreed that mongolism is not hereditary in the sense that hemophilia and color blindness are hereditary.^{1,2} Abundant evidence⁴ shows that the risk of mongolism is greater in mothers of advanced age than in those who are younger. There is also a higher frequency of mongolism in homozygote as contrasted with heterozygote twins.³ By some this is interpreted to mean that the ovum or sperm is defective. Early reports tending to implicate diseases like syphilis, tuberculosis, malaria and alcoholism² are inadequate to explain the large majority of cases. Indeed, no one etiology has been shown for the condition.

No cases have been reported that correlate minor maternal illnesses with the subsequent development of the condition. The recent discovery that maternal rubella may be followed by such widely disseminated and such severe fetal consequences as congenital cataract, anomalies of the heart, microcephaly and mental retardation^{4,5} has brought about a sudden change of perspective to both pediatricians and obstetricians. This change has to do with their point of view toward maternal infections that were once considered too trivial in their effect on the mother to have any bearing on fetal health. With this changed opinion in mind, we report 7 cases of intercurrent infectious disease observed during pregnancies that terminated in the delivery of a mongoloid baby. These are listed

in Table 1. The localization of the particular disease in 6 of the 7 cases at about the end of the second month of pregnancy is provocative. It is more so in view of the long recognized association of mongolism with such congenital deformities as cleft palate, syndactyly and imperforate anus, which date from about the same period of fetal life.⁶ We believe that further epidemiologic studies are indicated to show whether acute maternal infections correlate with the subsequent development of mongolism.

Even if acute intercurrent infectious disease proves to be one factor in the etiology of mongolism, it probably accounts for only a small fraction of all cases. The problem of demonstrating such a factor is not dissimilar to that posed by the relation of tonsillectomy to subsequent poliomyelitis, tonsillectomy being shown to be a factor in a small fraction

TABLE 1 Data on Mothers of Mongoloid Babies Who Had Intercurrent Diseases during Pregnancy

AGE OF MOTHER	INTERCURRENT DISEASE	STAGE OF PREGNANCY
37		11*

29*	Mumps	2
47(†)†	Mastoidectomy	2
9	Pneumonia (in bed 2 wk.)	3
52	Grippe	6
27‡	Acute purulent otitis media and sinusitis (with vomiting)	2

*The information on this case was furnished by Dr. Richard C. Teet.
†Mother had pneumonia at birth of child and died.
‡On a diet during first month of pregnancy patient lost 15 pounds.
§Sinusitis occurred just prior to otitis. Mother was admitted to hospital because of vomiting necessitating intravenous administration of fluids.

of all cases (about 1 per cent). The relation was demonstrated not by the ratio of cases of poliomyelitis to tonsillectomies but by a significant pyramiding of the developing cases, ten to twenty days postoperatively.⁷

In determining the relation of intercurrent infectious disease to mongolism, the week of pregnancy in which the particular disease occurred is of statistical importance. Since there are forty weeks to a normal pregnancy, there is only one chance in forty for a given illness to occur in any particular week—if the phenomenon is a chance one. When a sufficient number of cases are assembled, the figures can be submitted to statistical analysis.

MEDICAL PROGRESS

PATHOLOGY*

TRACY B MALLORY, MD†

BOSTON

FOUR years have elapsed since I have had the privilege of recording progress in pathology for this series. During that period staffs of civilian laboratories were cut to the bone, and the demands of routine diagnostic work and year-round teaching under the accelerated program of medical education left little opportunity or energy for investigative work. To a considerable extent this was balanced by the necessity of pathological investigation of problems of military importance, a need largely cared for in this country by the farsighted policy of the United States Army in developing and progressively expanding the Army Institute of Pathology with its large corps of full-time workers and its part-time consultants. The unparalleled collection of anatomic material that has flowed into it from every corner of the globe has already permitted many studies of importance. A portion has already been published, publication of much more is imminent and study of the remaining material will occupy as large a corps of investigators as can be maintained for years to come.

Any attempt to survey the entire field of pathology for a four-year period would require such cursory treatment as to be completely valueless. A few features only have been selected because they seem to be of more than casual interest and importance.

Rheumatic Fever and Periarteritis Nodosa

One of the most interesting conceptions in pathology in recent years is the hypothesis advanced by Rich¹ that the lesions of periarteritis nodosa and rheumatic fever are the result of anaphylactic hypersensitivity. The possibility that rheumatic fever is a hypersensitive reaction had been entertained for many years by a variety of investigators, and the early literature was reviewed by Swift² and Gross,³

in 1929, and again by Coburn⁴ in 1931. Gross repeated many of the reported experiments with negative results. In succeeding years Klinge,⁵ Vaubel⁶ and Junghans⁷ each claimed to have produced lesions of the rheumatic type by sensitization of animals with horse serum, but their published illustrations were not convincing. Bruun,⁸ in 1940, repeated their experiments with only equivocal results and concluded that he had not reproduced a true analogue of the Aschoff nodule.

In 1942 Rich⁹ reported autopsies on 5 patients who had had serum sickness shortly before death, in all of whom vascular lesions characteristic of periarteritis nodosa were demonstrable. None of the patients had any symptoms suggestive of periarteritis prior to the acute terminal illness, and all the vascular lesions were fresh. Similar vascular lesions were also demonstrated in 2 patients who had had reactions to sulfonamide therapy.¹⁰ He concluded that vascular lesions of the periarteritic type can be a manifestation of the anaphylactic type of hypersensitivity.

In the following year Rich and Gregory¹¹ reported the experimental production of similar lesions. Rabbits were sensitized with one or more large doses (10 cc) of horse serum. On the fifth to the eighth day the animals developed fever and had a slight blushing of the skin, possibly equivalent to the urticaria of human serum sickness. All animals showed on skin test the immediate, anaphylactic type of hypersensitivity, some developing Arthus reactions with necrosis. They were sacrificed at periods ranging from seventeen to twenty-six days, and the majority showed arteritic lesions characteristic of various stages of periarteritis nodosa.

In an extension of this experiment the same authors¹ found in the hearts of 11 of 36 similarly sensitized rabbits lesions that reproduced closely the five supposedly pathognomonic features of acute rheumatic carditis. These are focal alterations of

*From the Department of Pathology and Bacteriology, Massachusetts General Hospital.

†Director, Department of Pathology and Bacteriology, Massachusetts General Hospital.

collagen, Aschoff nodules, focal and diffuse inflammatory lesions, focal alterations in cardiac muscle and verrucose valvular vegetations. In the experimental animals connective-tissue alteration was prominent in the endocardium near the valvular attachments, and nodules developed about the foci of damaged collagen composed of large cells with abundant usually basophilic cytoplasm, of which some were multinuclear, and others resembled Anitschkow myocytes. In a few nodules palisading of cells about the altered collagen was observed. These nodular foci were usually formed near the attachments of the valves. Perivascular inflammatory infiltrates were frequent, but nodule formation in the adventitia of arteries — a characteristic location in rheumatic fever — was not observed. Non-specific inflammatory lesions in the endocardium and pericardium were frequent. In 4 animals small foci of necrosis of cardiac muscle fibers were found. No actual vegetations with thrombus formation were noted, although the nodules frequently projected above the surface of the valve to give it a slightly warty appearance. The parallelism traced between the experimental lesions and the histologic findings in acute rheumatic fever is impressive, if not complete, and the excellent illustrations guarantee the objectivity of the verbal descriptions. Evidence for the anaphylactic character of still another rheumatic lesion was furnished by the same authors by a demonstration of the essential similarity of the pulmonary injury following sulfonamide sensitization and that of rheumatic pneumonitis.¹²

The greater success of Rich and Gregory, in comparison with their predecessors, in reproducing histologic features closely simulating those of rheumatic fever in human beings may well have been due to their clear distinction between the anaphylactic and tuberculin types of hypersensitivity and their selection of more appropriate sensitizing regimens. There can be little hesitation over accepting their hypothesis regarding periarteritis nodosa, in which clinical evidence of hypersensitivity, such as eosinophilia or asthmatic paroxysms, is frequently present. Even here, caution is suggested by the reports of periarteritis developing in rats and dogs made hypertensive by clamping of the renal artery¹³ or by wrapping of the kidney in silk.¹⁴ Despite the close parallelism between the symptomatology of rheumatic fever and serum sickness the usual stigmas of allergy are lacking in the former disease, and direct proof of anaphylactic sensitization in rheumatic fever in the human being has yet to be advanced. Studies such as those of Coburn⁴ with streptococcal antigens should be repeated with attention to immediate rather than delayed types of skin reaction.

Acute Disseminated Lupus Erythematosus

Acute disseminated lupus offers so many general features of similarity to and so many details of difference from rheumatic fever that comparison

of the two diseases fascinates clinicians and pathologists alike. A new angle of comparison has been advanced by Klemperer, Pollack and Baehr¹⁵ in a continuation of the pathological studies on lupus that have occupied the laboratory of the Mt. Sinai Hospital for many years. On the basis of a review of the 35 cases that have come to autopsy in that institution, with particular study of the last 20, they have reached the conclusion that the thesis formerly advanced — that lupus is fundamentally a diffuse vascular disease¹⁶ — is no longer tenable. They now present evidence that the basic pathologic lesion is a characteristic type of focal connective-tissue degeneration. All elements take part in the reaction. The mucoid ground substance, ordinarily hardly visible, becomes evident as a swollen homogeneous interfibrillar mass. The collagenous fibers assume a straight, rigid, irregularly thickened appearance and become deeply eosinophilic, assuming the character often designated as fibrinoid. The fibroblasts show degeneration, proliferation and even necrosis. Inflammatory reaction, although variable, is non-specific in type and relatively inconspicuous, and in the authors' words, "the alterative phase of the process is far out of proportion to the exudative." This is in marked contrast to rheumatic fever, a disease in which collagenous degeneration has long been recognized as one of the most important pathologic features, but in which active inflammatory reaction of a specific character about the foci of altered collagen is constant. The involvement of serous cavities is considered secondary to the connective-tissue degeneration of the limiting membranes, rather than to primary mesothelial involvement as Gross¹⁷ suggested. Again, the first change noted in the endocardium and valves was in the connective tissue rather than in the endothelium. The so-called "wire-loop" changes of the glomerular tufts in the kidney are evidently a primary change of the collagen of the capillary basement membranes, and even the focal glomerulitis of other cases can be so interpreted. Vascular lesions, although seen most often in the kidneys, are observed rather frequently in other organs. The mildest recognizable change is a deposit of fibrinoid material within the intima, and later between the muscle fibers of the media and in the adventitia. It is usually accompanied by fibroblastic proliferation. Endothelial damage is definitely considered secondary, in contradiction to previous work from this same laboratory that considered it primary.¹⁸ In severe lesions secondary necrosis of the entire vascular wall may occur, closely simulating the vascular lesions of malignant hypertension or even periarteritis nodosa.

Connective-tissue changes of the type described are much less conspicuous in the skin, although they do occur. It is doubtful if many dermatopathologists would admit that they were primary. In the spleen, fibrinoid degeneration was unusual, but another form of connective-tissue change was found

in 19 of 20 cases. This consists of periarterial fibrosis limited to central and penicillary arteries in the form of concentric rings of dense collagen fibers. This lesion is sufficiently specific to have considerable diagnostic value. Unaccounted for by the theory of primary collagenous injury is the extensive involvement of lymphoid tissue frequently observed.

Rheumatoid Arthritis

Joint lesions so dominate the clinical picture of rheumatoid arthritis that comparatively scant attention has been given to the possibility of involvement of other organs and tissues. The possibility of cardiac involvement has been raised by Baggenstoss and Rosenberg^{18, 19}. Cardiac lesions indistinguishable from ordinary rheumatic carditis were found in several cases of rheumatoid arthritis, and in 2 the histologic picture was similar to that of rheumatoid nodules. Steiner et al.²⁰⁻²² have recently shown that peripheral nerves and muscles are frequently affected. The lesions in both nerves and muscle consist of small aggregates of mononuclear cells, lymphocytes and plasma cells predominating but with occasional macrophages. There is usually no evidence of any core of necrotic collagen as in the rheumatoid nodules, and no palisades of epithelioid cells develop. The foci are found in the perineurium and perimysium of nerves and muscles respectively. Since there is no evidence of axonal or myelin-sheath degeneration, it seems improbable that nerve function is impaired. In the muscles, atrophy was frequently observed, but the evidence for attributing this to the inflammatory foci is not convincing.

In discussion of Steiner's²² paper Clauson reports the results of biopsies of the deltoid muscle from 70 cases of rheumatoid arthritis. In more than half he was able to find lesions similar to those described by Steiner. He also found indistinguishable lesions in a few cases of rheumatic fever.

Atypical Pneumonia

One of the great advantages of a central institute of pathology, such as that fostered by the Army in Washington, is in the study of the pathology of diseases with a low mortality. Few hospital laboratories, for instance, have had the opportunity of studying more than one or two examples of atypical pneumonia. The Army Institute of Pathology has autopsy material from 90 cases in which that diagnosis had been made on clinical grounds. Many were inadequately studied, and others were complicated by secondary bacterial infection, but Golden²³ was able to select 21 entirely acceptable cases for analysis. In this group of cases focal bronchiolitis was a constant finding. The lumens contained frank pus, mucoid secretions and desquamated epithelial cells, sometimes in an advanced stage of disintegration. Ulceration of the mucosa was not rare. Bacteria were absent in most cases,

and when present were neither numerous nor uniform in type. The affected bronchioles were dilated, and their walls were infiltrated with mononuclear cells. This inflammatory infiltrate tended to spread radially into the adjacent tissues, such as the alveolar walls and the interlobular septums. The alveoli were in part aerated, focally atelectatic and occasionally filled with protein-rich edema from which hyaline membranes precipitated on the alveolar walls. They were always relatively free from polymorphonuclear infiltration. Fibrinous pleuritis was unusual, in contrast to its frequency in bacterial pneumonias. In cases of longer duration foci of squamous-cell metaplasia frequently appeared in the bronchi, and the alveoli sometimes became lined with columnar epithelium.

The type of pneumonitis described may fairly be classed as an interstitial pneumonitis. As McCordock and Muckenfuss²⁴ pointed out, viruses that involve the lung tend to produce this type of pneumonitis. Interstitial pneumonitis cannot, however, be considered reliable evidence of virus infection, since it occurs in conditions as different as scrub typhus, Q fever and even histoplasmosis.²⁵

Scrub Typhus

Until the American invasion of the South Pacific, scrub typhus was an unknown disease to most American physicians, and few would even have been able to identify it with the fascinatingly alliterative *tsutsugamushi*, which had lingered as a mere name among the vaguer recollections of medical-school days. From the material of the Army Institute of Pathology, Allen and Spitz²⁶ have been able to describe thoroughly the pathology of the disease and to compare the lesions with those of the related rickettsioses: epidemic typhus, Rocky Mountain spotted fever and Q fever.

A noticeable primary lesion, known as the eschar, usually develops at the point of the mite bite. This is often frankly suppurative and probably represents a combined reaction to the inoculated rickettsias and to the irritating secretions of the mite. In contrast to epidemic typhus and still more so to spotted fever, there is relatively little evidence of vascular damage in scrub typhus. Cerebral involvement is qualitatively similar to that in epidemic typhus, but the lesions are less numerous and the individual nodules are somewhat smaller and less conspicuous. Interstitial myocarditis, in contrast, is more constant and severe in scrub typhus than in either the epidemic disease or in spotted fever. In view of the intensity of the interstitial reaction, remarkably little evidence of muscle-cell involvement is observed. Endocardial involvement was found in a third of the cases. Interstitial pneumonitis of marked degree is not rare in scrub typhus, whereas it is seldom evident in epidemic typhus or spotted fever. In this respect the disease shows an apparent relation to Q fever, in which pneumonitis

is often the predominating feature. One other point of differentiation appeared in the lymph nodes, which frequently show necrosis in scrub typhus but rarely do so in the other rickettsial diseases.

Injury Due to Cold

The recent war offered abundant opportunities for studying injury due to exposure to low temperatures. Several closely related syndromes have been described under such titles as "trench foot,"²⁶ "immersion foot"²⁷ and "high-altitude frostbite"²⁸ in American, British and German journals. The similarities of clinical and pathological findings are great, and the differences inconstant, suggesting that the underlying tissue injury is similar regardless of the type of exposure and whether or not actual freezing of the tissue occurs. The most complete pathological study to date is that of Friedman²⁶ from the Army Institute of Pathology based on 14 cases of trench foot. The findings closely parallel those of Siegmund²⁹ in cases of frostbite on the German-Russian front and of Blackwood²⁷ in cases of immersion foot.

The initial reaction following cold injury of all types is a prolonged period of vasoconstriction. This is followed by a stage of intense hyperemia. In the majority of severe cases this is accompanied by edema and frequently by exudation and hemorrhage into the tissues. In severe cases necrosis develops, leading to wet or dry gangrene. Pathological investigation has been hampered because surgery is delayed as long as possible, and most amputation material has shown only late stages of the process. Friedman was fortunate in having at his disposal several extremities from men dying of other causes shortly after developing trench foot. He found in this early material constant changes in the skin, subcutaneous fat, blood vessels and nerves. In the skin intercellular and intracellular edema was found in the malpighian layer in the earliest stages, later, vesiculation or frank necrosis and mummification occurred. The skin appendages were often involved, particularly the coil glands. Degeneration of collagen and elastic fibers, which was frequent in the later stages, was inconstant in the earlier ones. Involvement of the deeper portion of the subcutaneous fat tissue was constant and surprisingly extensive in view of earlier reports. In acute stages leukocytic infiltration was prominent, and edema and even fibrinous exudation into the interlobular fibrous septums were observed. Later, atrophy of fat lobules, accumulation of foam cells and replacement fibrosis became frequent. Occasionally, oil cysts formed. It seems probable that the loss of this protective layer had much to do with the long persistent functional disability in some cases that escaped gangrene. Vascular abnormalities were constant. In the early stages extreme dilatation and engorgement of small vessels were evident, frequently in association with peri-

vascular hemorrhages. The next stage of involvement was the appearance of thrombotic masses of agglutinated red cells, relatively free from platelet debris and fibrin in comparison with ordinary thrombi. Angitis, although usually present, was not particularly severe. In later stages (thirty to forty days), organization of thrombi and endarterial intimal proliferation were usual. Muscle changes were inconspicuous in the early cases, but extensive atrophy was noted in late lesions. Nerves in the early cases showed swelling, edema and focal degeneration of axis cylinders and myelin. In later stages demyelination and perineurial fibrosis were observed. White and Warren³⁰ suggested that the latter was responsible for the persistent pain noted in certain cases. It was not possible, on the basis of the pathological evidence, to decide whether vascular or neural changes were primary.

Epidemic Hepatitis and Homologous Serum Jaundice

The pathology of epidemic hepatitis was comparatively unknown until the outbreak of World War II. Jaundice due to massive necrosis of the liver had been recognized as early as 1842 by Rokitsansky,³¹ who first described and named "acute yellow atrophy." It was, however, regarded as a uniformly fatal disease. Catarrhal jaundice was considered a benign and totally unrelated malady. Although the Scandinavians Flindt,³² Linstedt,³³ Ehrström³⁴ and Wallgren³⁵ and the Englishman Cockayne³⁶ successively pointed out at intervals from 1890 to 1930 the parallelism of incidence between catarrhal jaundice and atrophy of the liver, general medical opinion was essentially uninfluenced by their observations. The world-wide pandemic of hepatitis in the soldiers of all belligerent countries in the recent war has provided unlimited material for study. From the spring of 1942 to April, 1945, material from 296 fatal cases was submitted to the Army Institute of Pathology. The first 118 of these were reported by Lucké³⁷ in 1943. The succeeding 178 cases were subsequently reviewed by Lucké and Mallory.³⁸

Most fatal cases of hepatitis can be readily classified into one of two types, subacute and fulminant, which show corresponding variations in clinical and pathological findings. The subacute type was exemplified by the series of cases developing in the American Army in 1942, which was reported by Lucké. None of the patients died in less than ten days, a few survived for one hundred days or more, and the survival period in 60 per cent ranged from twenty to fifty days. In these cases the liver showed extensive but irregularly distributed necrosis and numerous, often large, yellow or green foci of regeneration. This is the condition that for years was classified as "idiopathic acute yellow atrophy." In the second series of cases, reviewed by Lucké and Mallory, the majority (53 per cent) of patients died in less than ten days, many in as short a period

as three or four days, and a few even before the onset of jaundice. In such cases the symptomatology is often predominantly cerebral. The hepatic necrosis is diffuse and massive and no evidence of regeneration is seen, but the process has occurred so fast that the liver has had little time to shrink and is often only slightly reduced in size. Frequently, the gross appearance is that of an exaggerated "nutmeg liver." Cases of this type have also been reported by Wood³⁹ in material derived from personnel of the United States Navy. Despite the difference in the two types, enough points of similarity and enough transitional forms are observed to make it certain that they are not two diseases but represent a wide range of reaction to the same fundamental disorder.

The significant pathology of the disease is centered in the liver. In both types two features are constantly found—extensive degeneration and necrosis of liver cells and inflammatory reaction, most evident in an infiltration of the periportal connective tissue, with histiocytes and smaller numbers of other wandering cells. The necrosis is widespread and uniform in the fulminant cases, and regeneration is minimal or absent. Of particular interest are the patients dying in two to four days, either before or shortly after the onset of jaundice. Total destruction of the liver parenchyma has already occurred, and it is difficult to escape the conclusion that severe hepatic involvement must have antedated the first clinical symptoms.

It is of interest to compare the clinicoanatomic classification of hepatitis described above with current epidemiologic classifications. Four types of the disease are recognized from the latter point of view: the sporadic and epidemic forms of the "naturally" acquired disease, homologous serum jaundice and arsphenamine hepatitis. No clinical differences have been established and studies of nonfatal cases by the biopsy technique⁴⁰⁻⁴² have likewise failed to provide grounds for distinction. Lucké and Mallory found that a majority of their fulminant cases occurred in wounded men who had received plasma or whole-blood transfusions from fifty to ninety days before the onset of symptoms of hepatitis. This range is within the accepted incubation period of homologous serum jaundice. On the other hand, nearly a third of the fulminant cases appeared in men who had never received infusions of human plasma. These findings were balanced, however, by Lucké's cases in 1942, all of which were of the subacute variety despite the fact that the majority were cases of homologous serum jaundice secondary to yellow-fever vaccination. It is evident that the spontaneous and the homologous serum cases may each run either a subacute or a fulminant course and that the method of infection is not the explanation of variations in clinicoanatomic type. If different viruses are involved,^{43, 44} they produce identical end results.

Since this report was submitted numerous other important studies from the Army Institute of Pathology have been published.⁴⁵

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

Weekly Clinicopathological Exercises

FOUNDED BY RICHARD C CABOT

TRACY B MALLORY, M D, *Editor*

BENJAMIN CASTLEMAN, M D, *Associate Editor*

EDITH E PARRIS, *Assistant Editor*

CASE 33121

PRESENTATION OF CASE

First admission A sixty-four-year-old English wool dealer was admitted to the hospital because of severe nausea and vomiting of one day's duration. He had had no pain, hematemesis or any change in bowel habits.

Physical examination was entirely negative except for a blood pressure of 170 systolic, 95 diastolic. Two urine examinations showed a +++ test for albumin with many white cells and bacteria in the sediment. Examination of the blood showed a hemoglobin of 14.2 gm and a white-cell count of 11,200, with 84 per cent neutrophils. A gastrointestinal series revealed a diverticulum projecting medially from the second portion of the duodenum. Recuperation was spontaneous, and the patient was discharged four days after admission.

Final admission (eight months later) During the night before admission the patient became restless and nauseated but did not vomit. At 7.30 a.m. a severe, sharp pain, "like a rifle shot," developed under the "breast bone" and in the throat. This was associated with shortness of breath, and about four hours later the pain radiated down the arms and into the back between the scapulas.

Physical examination revealed a pale man who was slightly obese but not short of breath. The pulse was 112 and of good quality and the blood pressure was 128 systolic, 90 diastolic. The neck veins were distended and pulsating while the patient was lying down. The heart did not appear enlarged. The aortic second sound was equal in intensity to the pulmonic second sound, and there were no murmurs. The cardiac sounds were somewhat decreased in intensity. The chest was clear, and the abdomen normal. There was slight cyanosis of the

finger-nails, but no peripheral edema. An electrocardiogram three and a half hours after the onset of the attack was within normal limits. At 1.30 p.m. on the day of admission the patient had a convulsion, the pulse became weak and irregular and the blood pressure could not be obtained. Oxygen and 0.5 cc of adrenalin were administered, but the pulse finally became imperceptible and the patient expired.

DIFFERENTIAL DIAGNOSIS

DR CONGER WILLIAMS From the data presented, I cannot reach any conclusion about the illness that caused the first hospital admission, and I doubt whether this episode had any relation to the final acute illness. Possibly, the urinary findings can be explained by urinary infection, although a widespread disease affecting both the kidneys and the heart, such as periarteritis nodosa, should not be overlooked. The one value of the examination at the first admission is to establish the fact that the blood pressure was slightly elevated. It may be of some importance in determining the cause of the final episode.

At this point it is well to consider what conditions caused the acute pain in the chest. First of all, in a man of this age, the possibility of coronary heart disease with acute infarction must always be considered. In favor of that diagnosis is the fact that the pain was located beneath the sternum and radiated up into the throat, later going into the arms. This may have happened when the pain increased in intensity. The drop in the systolic blood pressure to 128 from the former level of 170 is also consistent with infarction. Against the diagnosis is the quality of the pain, which was described as sharp. The characteristic pain of myocardial infarction is dull or squeezing, often described as a sensation of pressure. Some patients in describing pain, however, use the adjective "sharp" to mean severe rather than knife-like. It is possible that some confusion arose merely from the choice of terms in description. Another point against the diagnosis of infarction is the apparent suddenness of onset of severe pain, although the restlessness during the preceding night may have marked the real beginning of the trouble. Also, whereas radiation of pain into the back occurs with myocardial infarction in a fair percentage of cases, I think that radiation of pain from the sternum into the neck, down both arms and into the back — during the course of one attack — is rather unusual. Repeated attacks may occur in which the radiation of pain

varies, but I believe that this was an unusually wide referral of pain for a case of infarction.

Certainly, in any acute emergency giving rise to chest pain, the possibility of dissecting aortic aneurysm should be considered. In the first place we know that this patient had hypertension, which can almost be called a necessary prelude to dissection. Secondly, the onset and intensity of the pain in the chest are both more in favor of dissecting aneurysm than of myocardial infarction. If it is assumed that the first pain, described as substernal and radiating into the neck, was produced by involvement of the mouths of the coronary arteries in the progress of dissection, it might be said that the pain in the back, instead of being referred pain, represented extension of the dissection along the course of the aorta down into the descending portion. Another point that should be mentioned and is perhaps slightly against the diagnosis although not ruling it out is the fall of the blood pressure. Usually, in acute dissection the blood pressure is surprisingly well sustained. I shall say more about that later.

Apparently, in the history a statement was made about shortness of breath. That should be clarified. The patient may have meant that he had sufficient substernal discomfort to produce a sensation of shortness of breath, which is quite different from dyspnea. I assume that he did not have dyspnea because it was not evident on physical examination.

The finding of distended and pulsating neck veins is not necessarily significant with the patient in the horizontal position. The fact that this man may have had increased venous pressure should be considered, however, and its implications should not be overlooked. If he actually had an increase in peripheral venous pressure, what conditions were responsible? I should like to mention three, as being the likeliest. The first is congestive heart failure, for which evidence is practically nonexistent in this case. Although shortness of breath was mentioned, it was not observed on physical examination. The lungs were clear, and we have nothing except this one finding to suggest failure of the myocardium. Another condition that produces an acute, sudden increase in peripheral venous pressure is cardiac tamponade. This, of course, is a frequent complication of dissection of the aorta that progresses down through the root of the aorta, with rupture into the pericardial sac. Also, the break may occur above the base of the aorta but below the attachment of the pericardium to the aorta. Therefore, that is a possibility. If the leak is small, death does not necessarily ensue immediately — the patient may survive for several hours. If there is an increase in venous pressure as a result of acute cardiac tamponade, pulsus paradoxus is usually evident on examination. It is possible to miss a paradoxical pulse, however, if the measurement is made simply by palpation of the radial artery. It is

sometimes necessary to use auscultation to detect pulsus paradoxus. Acute pericardial tamponade would also explain the fall in blood pressure. The third possibility to explain the increase in venous pressure is pulmonary embolism. I find nothing to support that diagnosis, and if this man had pulmonary embolism, the widespread pain must be explained on the basis of a secondary myocardial infarction. Pulmonary embolism complicated by myocardial infarction is not too rare, but I discard that possibility in this case.

The normal electrocardiogram is slightly against the diagnosis of myocardial infarction but by no means rules it out. It is possible to have a large infarction with no change in the electrocardiographic findings for hours or even days.

There are several possibilities to explain the sudden exitus. Dissection could have involved the cerebral vessels, producing convulsions. Or this may have been caused by cardiac arrest, either from auriculoventricular block — the so-called "Adams-Stokes phenomenon" — or from ventricular fibrillation. Another possibility is a sudden massive hemorrhage that, by producing acute cerebral anoxia, may also have caused the convulsions. A frequent termination of aortic dissection is rupture into the pleural cavity, with massive hemorrhage. Besides aortic aneurysm and myocardial infarction, I considered the other conditions that one usually thinks of in the differential diagnosis of acute chest pain. Those included acute pancreatitis, which I discarded because of the absence of abdominal findings and also because of the absence of vomiting on the final admission. I do not believe that any of the acute pulmonary episodes, such as pulmonary collapse, pneumothorax and mediastinal emphysema, explain the history as given or the radiation of pain into the arms, neck and back.

In conclusion my diagnosis is dissecting aortic aneurysm, mostly on the basis of the history. I realize that several of the positive findings one likes to see, such as the rapid development of an aortic diastolic murmur and absent pulsations in one or more of the limbs, were not present.

DR BENJAMIN CASTLEMAN Have you anything to add, Dr White?

DR PAUL D WHITE The fact that the neck veins were pulsating as well as distended helps to rule out any large mass, such as hemorrhage, compressing the mediastinal vessels. In such a case I should expect that there would be distention but not pulsation in the vessels.

CLINICAL DIAGNOSIS

Dissecting aneurysm of aorta?

DR WILLIAMS'S DIAGNOSIS

Dissecting aneurysm of aorta

ANATOMICAL DIAGNOSES

Dissecting aneurysm of aorta, with rupture into pericardium
Cardiac tamponade
 Chronic pyelonephritis left kidney

PATHOLOGICAL DISCUSSION

DR CASTLEMAN Autopsy showed everything that Dr Williams predicted. This was a dissecting aortic aneurysm. The intimal tear had occurred about 15 cm above the aortic valve and had dissected proximally down around the coronary mouths. Although at the time of autopsy little blood was found in the dissecting channel, there was separation down to and around the coronary mouths, which may explain the anginal attacks. The aneurysm had extended distally along the arch and the descending aorta into the left iliac artery. It surrounded and extended into one of the renal arteries. The external tear was not easy to make out, but we know that it occurred within the pericardium because the pericardial cavity was filled with blood. The fact that we could not find the actual tear indicates that there may have been a slow leak over a period of two or three hours. That might account, as Dr Williams suggested, for the distention of the neck veins. Another interesting finding—one that we have seen in a number of cases with pericardial hemorrhage—was extravasation of blood into the adventitia of the pulmonary arteries. This blood extended along and formed a hemorrhagic extravasation in the subpleural space, especially in the interlobar septums. This may also have added to the distention of the neck veins.

The only other finding of note was a chronic left pyelonephritis, which probably accounted for the urinary findings found at the final admission.

DR HOWARD B. SPRAGUE There is one point of interest in this case that I wish to bring out. I did not see the patient myself, but asked Dr William C. Bridges to see him on an emergency call. I discovered later that this man had attended an annual banquet of the wool trade on the previous night. His friends told me that he appeared perfectly well and that they could not understand how such a healthy person could be dead the next day. He was active in business, making frequent trips abroad, and was free from symptoms. The incident tends to spread the belief among laymen that heart disease strikes without warning. As a matter of fact, most patients dying of coronary disease have warnings of an anginal character for some time prior to the fatal attack. Lack of such symptoms is further evidence, therefore, in favor of dissecting aneurysm as against coronary occlusion, although the rule does not hold in every case. Whether or not the heavy banquet was a factor in precipitating the aortic rupture, one cannot say.

DR WHITE It is of some importance, particularly in treatment, to differentiate as soon as possible myocardial infarction and dissecting aortic aneurysm. From the standpoint of prognosis the chances are ten to one of recovery from myocardial infarction and ten to one against recovery from a dissecting aneurysm. That is approximate, of course.

CASE 33122

PRESENTATION OF CASE

A fifty-year-old woman was admitted to the hospital because of palpitation, dyspnea and orthopnea.

She had been treated by a physician for high blood pressure and "sick headaches" for many years. Five years before entry, because of profuse menstrual periods and intermenstrual bleeding, a hysterectomy had been performed for fibroids of the uterus. Adrenalin given preoperatively caused palpitation. After operation the physician told the patient that she must have had rheumatic fever in childhood because the aortic valve was "all eaten away" and the heart was "greatly swollen." An attack of phlebitis in the left leg subsequently forced the patient to remain in bed for a month. At that time she began to have orthopnea and exertional dyspnea and palpitation. There was no ankle edema, cyanosis or cough. Digitalis was administered, and the dyspnea cleared, the patient was able to return to her household duties after a month or two. She continued to notice exertional dyspnea and palpitation, however, and was forced to lead a rather sedentary life. Her condition remained unchanged until four months before admission, when the lower teeth were extracted, and a week or two later there was a sudden brief attack of nausea, a dry hacking cough, soreness in the ribs and fever. The pounding of the heart became marked, and a severe ache developed in the right knee and calf, extending to the toes, which became swollen. The pain in the knee cleared a few days later, but there was persistence of fever and malaise. The patient was hospitalized and given penicillin, with considerable relief, but the nausea persisted when she returned home. She remained on a liquid diet because of inability to swallow solid food. She had frequent green loose stools that started while she was in the hospital and persisted despite the fact that for years previously she had taken daily laxatives because of constipation. She returned to the hospital, where x-ray studies of the stomach, bowel and gall bladder were reported as negative, and penicillin was again given for a week. She continued to have palpitation, exertional dyspnea, night sweats, orthopnea and dysphagia. A week before admission exquisite tenderness developed in the left calf and ankle and the left toes. The patient stated that, according to her physician, in the few weeks prior to admission the blood pressure had dropped to normal.

The past history revealed no definite rheumatic fever, chorea or scarlet fever. An operation for a

ruptured appendix had been performed about fifteen years previously. The patient had had two pregnancies, the first child died in early infancy, and the second did not survive a cesarean section. A sister had died of what had seemed to be carcinoma of the stomach.

On physical examination the apical impulse was 9 cm from the midsternal line in the fifth interspace. There were a high-pitched, Grade III apical systolic murmur, a loud blowing systolic murmur at the base, loudest at the aortic area and transmitted to both sides of the neck, and a systolic thrill in the aortic and pulmonic areas. One observer heard a diastolic murmur in the pulmonic area. There were scars of the right rectus muscle beneath which a vague doughy mass that felt like adhesions was noted. Marked tenderness in the right upper quadrant just beneath the costal margin prevented palpation of the liver, but to percussion the liver did not appear enlarged. Light palpation in the right upper quadrant elicited rebound tenderness in the left upper quadrant. Scattered small red lesions, a few of which resembled petechiae, were noted in the skin. A small petechia with a white center was noted beneath the conjunctiva of the right lower lid. The left leg was warmer than the right. Both calves were tender when squeezed, the left more so than the right, and the left ankle was swollen and hot, without pitting edema. The ankle was quite tender. The toes of the left foot were markedly red and exquisitely tender, with erythematous patches, measuring 1 to 2 mm in diameter, over the left ankle and lateral aspect of the foot. Homans's sign was negative. There was no limitation of motion, and adequate pulsations were felt in the dorsalis pedis arteries bilaterally. There was questionable early clubbing of the fingers and toes.

The temperature was 99.6°F, the pulse 100, and the respirations 22. The blood pressure was 110 systolic, 64 diastolic.

Examination of the blood revealed a red-cell count of 5,150,000, with a hemoglobin of 13 gm, and a white-cell count of 10,200, with a normal differential count. The urine was normal. Plain films of the chest and abdomen were normal, the liver margin appeared normal. The total protein was 7.3 gm, the nonprotein nitrogen 30 mg, the uric acid 3.5 mg and the fasting blood sugar 107 mg per 100 cc. An electrocardiogram was normal on the fifth hospital day.

While the patient was in the hospital the blotches and the tenderness subsided somewhat, and a subsequent observation revealed absent pulsations of the right dorsalis pedis artery but equal pulsations were felt in the popliteal and femoral arteries on both sides. Blood cultures taken on the fourth hospital day grew colonies of alpha-hemolytic streptococcus. A week later the clubbing of the fingers became more pronounced, but no new petechiae developed. On the twelfth hospital day

examination of the heart revealed a Grade III aortic systolic murmur, with a thrill, and a Grade II aortic diastolic blow over the left sternal border, with no definite separate mitral murmurs. The hemoglobin at that time was 8.5 gm per 100 cc. Penicillin was given in a continuous drip starting on the sixteenth hospital day. On the eighteenth hospital day, however, the temperature rose to 103.5°F, and the patient was somewhat sleepy but euphoric when aroused. There were no localizing neurologic signs, but the following morning the patient complained of numbness of both hands, and there was some diminished tactile and position sense, especially on the left. She seemed somewhat confused throughout the day and spilled a glass of water on two occasions, presumably from the left hand. A test of the alpha-hemolytic streptococcus isolated by blood culture revealed that it grew in 0.25 units of penicillin per cubic centimeter and was inhibited by 0.5 units per cubic centimeter. Consequently, the penicillin dosage was increased to 1,000,000 units a day by intramuscular drip. Two days later the hands had cleared considerably, and a week later the patient seemed to be recovering. No new symptoms had developed.

The patient continued to run a temperature, occasionally as high as 101.5°F during the next few weeks, and on the forty-first hospital day she developed intermittent abdominal cramps, which were largely periumbilical, and by evening she vomited 400 cc of watery material. Examination revealed no acute abdominal tenderness or tympany, and peristaltic rushes could be heard concomitant with the pain. The temperature was 103.5°F, and the white-cell count 13,000. A plain film of the abdomen on the next day revealed distended loops of small intestine and a suggestion of a soft-tissue mass in the pelvis above the bladder shadow, more on the left than on the right, at which site the distention of the small bowel stopped. Fecal material was noted in the colon. Re-examination after the use of a Harris tube revealed the small intestine to be markedly deflated. Because of the continued pain and a rise in the white-cell count to 17,700, an exploratory laparotomy was done and adhesions were lysed. She appeared to recover from the operation, but spiking fevers continued on occasion. On the sixth postoperative day she had a mild headache, with numbness of one finger, and fever. On the following day the patient woke at 1.00 a.m. yelling incoherently. She was disoriented and recognized no one. She vomited recently ingested material once and put her hand to the left side of her head in a manner suggesting pain in this area. The neck was slightly stiff. The pupils were equal, the right pupil reacted sluggishly to light. The motor power in the extremities seemed equal, and she reacted to painful stimuli. No abnormal reflexes were encountered. She died about six hours later. The last positive blood culture had been obtained on the fifteenth

hospital day, and twelve subsequent blood cultures had been negative

DIFFERENTIAL DIAGNOSIS

DR JAMES H CURRENS The symptoms of palpitation, dyspnea and orthopnea are indicative of heart disease, probably due to limited myocardial reserve.

After the operation a physician told the patient that she must have had rheumatic fever in childhood because the aortic valve was "all eaten away" and the heart was "greatly swollen" This was the first evidence of valvular heart disease and was discovered when the patient was forty-six years of age

It is of interest that she had phlebitis of the left leg as a complication of the hysterectomy Phlebitis, particularly on the left, is not a rare complication of a pelvic operation, particularly hysterectomy Whether she had pulmonary emboli at that time to account for the increase in exertional dyspnea and palpitation is difficult to determine Certainly, the history is not specific on that point

The past history indicated a decreased cardiac reserve, probably on the basis of a decreased reserve of the left ventricular myocardium over a period of five years The appearance of fever two weeks after a dental extraction is important The fact that she developed fever and did poorly after the extraction of several teeth is a strong indication of the hazard of dental extraction in the presence of valvular heart disease It is our practice to give penicillin as a prophylactic measure to people with valvular and congenital heart disease before and for at least twelve hours after dental extractions I think that cough may be a somewhat neglected symptom in heart disease, but I fail to associate the cough in this patient with the subsequent events

It would be of interest to know whether the patient had pain with the diarrhea Presumably, she had none The night sweats are probably significant I interpret them as evidence of continued infection Tenderness in the left calf in the presence of a history of phlebitis of the left leg strongly suggests the recurrence of a thrombophlebitis in that leg

One wonders if the previous hypertension was merely systolic hypertension, possibly associated with some nervousness and palpitation of the heart The diastolic blood pressure of 64 is certainly normal, but in view of the findings it may have indicated a mild degree of aortic insufficiency

"The apical impulse was 9 cm from the midsternal line in the fifth interspace" Unfortunately, we do not know the position of the midclavicular line Since the impulse was in the fifth interspace, however, there was probably relatively little cardiac enlargement. I think that the auscultatory findings were quite characteristic of aortic stenosis as was the transmission of the systolic murmur to the apex The presence of a thrill in the pulmonary area is somewhat unusual, but if the thrill is strong enough,

it could be palpated well over the sternum and presumably on both sides of the sternum One observer heard a diastolic murmur in the pulmonic area That is probably a significant finding in view of the subsequent clear-cut aortic diastolic murmur

The vague doughy mass that felt like adhesions was a remarkable observation, but in view of the subsequent development of intestinal obstruction it presumably was correct

In any cardiac patient with pain or tenderness in the right upper quadrant one must think of liver congestion There is not much evidence in the physical findings, however, to suggest either systemic or pulmonary congestion Tenderness in the left upper quadrant, although the spleen was not palpable, may have been due to splenic infarction The other possibility, I suppose, is a mycotic aneurysm, but it is rather difficult to see how a mycotic aneurysm of the lower aorta or mesenteric artery could account for such pain

The observation of scattered small red lesions, a few of which resembled petechiae, is important if the diagnosis of subacute bacterial endocarditis is considered, and there is evidence strongly in favor of such a diagnosis I should interpret the pain in the left calf as having been due to phlebitis of the leg Homans's sign was negative That sign, however, is usually an early indication of phlebitis of the leg, so that it might easily be absent later on The finding of a petechia beneath the conjunctiva of the lower lid is an important positive sign when one is considering bacterial endocarditis The same thing should be said of the early clubbing of the fingers and toes

The laboratory data were normal throughout except for the borderline hemoglobin

It is unusual for an x-ray film of the heart to be normal in a person with the symptoms that this patient had I think that we had better see the x-ray films

DR RICHARD SCHATZKI In this film, which was taken ten weeks before death, the heart is not enormously enlarged, but I think that the left ventricle looks rounder than usual, as if there was some left ventricular hypertrophy

DR CURRENS Certainly, the heart was not greatly enlarged, and it makes me question to a large degree many of the symptoms that the patient had had in the past five years Left ventricular failure does not occur with a normal-sized heart She may well have had some cardiac neurosis complicating the organic heart disease

The disappearance of the pulsation of the right dorsalis pedis artery, with good pulsations above, suggests a small embolus in the right lower leg

The anemia may explain the more apparent aortic diastolic murmur that developed under observation Another explanation might be ulceration of the aortic-valve leaflets to allow greater insufficiency of the valve

On the eighteenth hospital day the temperature rose to 103.5°F, and the patient was somewhat sleepy but euphoric when aroused. A high temperature is an unusual finding in the presence of penicillin therapy. These findings are evidence, I should think, of embolism to the brain, resulting in "numbness of both hands and diminished tactile and position sense, especially on the left."

"A test of the alpha-hemolytic streptococcus isolated by blood culture revealed that it grew in 0.25 units of penicillin per cubic centimeter and was inhibited by 0.5 units per cubic centimeter." This indicates a moderately resistant organism and may or may not have been affected by the previous penicillin that the patient had received on two occasions.

I do not know how the patient died, since the record does not state what happened during the last six hours. She may have died in coma.

The primary diagnosis is certainly that of aortic valvular heart disease, with both stenosis and regurgitation. Although there was no history of rheumatic fever, rheumatic heart disease is the best bet so far as the etiology of the aortic stenosis is concerned. She was a little young for aortic stenosis presumably resulting from arteriosclerosis. I believe that this type of aortic stenosis is more frequent in men than in women. Another possibility is congenital heart disease with a bicuspid aortic valve. Perhaps the patient was too old for that, although patients with congenital bicuspid valvular disease live fairly long and not infrequently develop stenosis or regurgitation, or both.

The evidence for subacute bacterial endocarditis seems clear cut: fever, petechiae, anemia and bacteremia. There is good evidence for embolic phenomena to the brain and the right leg. The absence of splenomegaly certainly does not stand in the way of such a diagnosis. The complications of subacute bacterial endocarditis are of importance to consider. In patients who have been treated with penicillin in the last few years it has been possible to cure the bacterial infection in 65 to 70 per cent of cases if a sufficient amount was given. In 30 or 35 per cent of fatal cases, the patients die primarily of complications of one type or another, possibly of heart failure. The infection is rarely completely resistant if heroic doses of penicillin are used. In this case only 1,000,000 units of penicillin a day was given. If the infection is impossible to control, it is essential to increase the penicillin as much as possible. Doses as high as 30,000,000 or 40,000,000 units a day have been used. In this hospital I think that the largest dose used has been 10,000,000 units a day. Once penicillin is started it should be continued for at least three or four weeks. The two courses of penicillin for a week each before entry to this hospital were obviously ineffective in eradicating the infection, although they suppressed it temporarily.

The evidence for peripheral emboli is good. In bacterial endocarditis of the aortic valve, emboli occasionally enter a coronary artery.

I believe that this woman had aortic valvular disease with superimposed bacterial endocarditis and with embolic phenomena. It has been my impression that patients with bacterial endocarditis of the aortic valve are likelier to have emboli than those with infection on the mitral valve. The possibility of a mycotic aneurysm of the aorta, a cerebral artery, a mesenteric artery or an artery of the extremity remains good. A disturbing factor in this patient is that she continued to have fever and evidence of peripheral emboli. Mycotic aneurysms usually, of course, manifest themselves by rupture, resulting in a subarachnoid hemorrhage when the aneurysm is located in a cerebral artery.

Another possibility is that of active rheumatic fever. Perhaps 10 or 20 per cent of the cases with subacute bacterial endocarditis and rheumatic heart disease have evidence of active rheumatic fever during the course of the disease or at autopsy. It is conceivable that some of the pain in the left ankle and the continued fever were on the basis of active rheumatic fever. The joint pains, however, were not impressive, and one might expect evidence of more heart failure with active rheumatic fever. The electrocardiogram was normal, which is against active rheumatic fever, serious myocardial disease or hypertrophy. The evidence is quite good that the infection persisted either on the aortic valve or in an unrecognized mycotic aneurysm.

The fact that the organism was moderately resistant also suggests that penicillin did not cure the infection. Against such a diagnosis is, of course, the fact that the blood cultures were negative. It is conceivable that the infection had been suppressed temporarily by the penicillin but not eradicated. This observation was not infrequent in the use of the sulfonamides before the penicillin era, at which time the blood cultures often remained negative for days or weeks only to become positive again. Another possibility is a mixed bacterial infection of the aortic valve, which has been described by Organ and Poston*, conceivably penicillin might have eradicated only one of the organisms. I should interpret the final outcome in this patient as having been due to a persistence of infection either of the aortic valve or in a mycotic aneurysm.

She may or may not have had pulmonary emboli. The history is certainly not suggestive.

DR EDWARD F. BLAND: A low-grade fever during penicillin therapy sometimes disappears on cessation of the therapy and hence need not necessarily imply continued infection. Furthermore, even embolism may occur after the infection has been arrested.

*Organ, E. S. and Poston, M. A. Mixed infections in bacterial endocarditis. *Am. Heart J.* 23: 823-836, 1942.

DR CURRENS Have you ever seen a temperature of over 100°F with penicillin therapy for bacterial endocarditis?

DR BLAND I believe so

CLINICAL DIAGNOSES

Subacute bacterial endocarditis
Rheumatic heart disease
Cerebral embolus

DR CURRENS'S DIAGNOSES

Rheumatic heart disease, with aortic stenosis and regurgitation
Bacterial endocarditis, with either persistent infection or mycotic aneurysm

ANATOMICAL DIAGNOSES

Subacute bacterial endocarditis aortic valve
Cerebral mycotic aneurysm, with subarachnoid hemorrhage

PATHOLOGICAL DISCUSSION

DR TRACY B MALLORY Post-mortem examination showed a normal-sized heart, but there was evidence of old rheumatic heart disease — slight on the mitral valve and quite definite on the aortic valve, with enough deformity to have produced

stenosis and probably a little regurgitation. There were vegetations on the aortic valve that were larger and more pliable than one sees in purely rheumatic heart disease but not so active as those observed in a subacute bacterial endocarditis. The immediate cause of death was an extensive subarachnoid hemorrhage. It is rather interesting that we found few manifestations of embolism. One can almost count on infarcts of the spleen and kidneys in cases of bacterial endocarditis. Both these organs were entirely free from any gross evidence of embolism. We could not tell whether histologically the vegetations on the aortic valve showed evidence of healing, since we decided to sacrifice the histologic studies for bacterial studies. The entire material of the valve was ground up and extensively cultured, but we were unable to grow out any organisms from the valve substance, so that it appears to have been bacteriologically sterile.

DR SCHATZKI How thick was the left ventricular wall?

DR MALLORY Of normal thickness. The heart weighed only 300 gm — a little on the small side.

DR JAMES H TOWNSEND What was the cause of the subarachnoid hemorrhage?

DR MALLORY There was a mycotic aneurysm.

DR BLAND Were there any Aschoff bodies?

DR MALLORY No.

THE PROBLEM FAMILY IN BRITAIN

A RECENT editorial¹ expresses British concern for a lamentable social evil, the so-called "problem family" — a term used to describe a segment of the population sunk in poverty, ignorance and degradation, incapable of responding to improving influences and providing a reservoir of delinquency, vice and disease. Perhaps mindful of the record of Government participation in medical care and public health elsewhere in the British Commonwealth,² the editorial, although recognizing the need for some measure of corrective social legislation, points out that the apparatus for ameliorative action already exists and that a voluntary organization — the Society of Friends — has demonstrated an effective

approach to the situation treating the family as a unit, reconciling estranged members, rehabilitating the home and restoring self-respect. It endorses Brockington's³ program for reclaiming the problem family from hopeless destitution and degeneracy, this solution combines the authority of the magistrate and the personal, humanitarian approach of the social worker — the former places the family on probation and introduces the social worker, with whom the family co-operates in the hope of successfully completing the period of probation and thereby of retaining the children.

Brockington, observing that a great number of homeless children had been separated from their families because of parental cruelty, neglect and immorality, destitution, illegitimacy and lack of parental control, recommended that the problem family be reconstituted and placed under the supervision of health authorities before reaching the stage of enforced separation, and that authority be granted for registration of the problem family, rehabilitation of the home and appointment of special staffs for teaching and supervision. He further suggested that current legislation, with its tendency to break up the family, be amended to empower magistrates to remove the family as a unit to care and protection after the failure of probation, and emphasized the fact that delinquent children should be separated from their families only after child guidance and efforts to improve home conditions have failed.

The interest of the British medical profession in the problem family is to be commended. The constructive recommendations for prevention and amelioration without extensive social legislation merit careful attention in the United States, where similar families exist in disquieting plenty and where governmental paternalism is ever expanding. In medical sociology, as in other fields, organized medicine can influence the course and extent of Government intervention.

PREVENTABLE CANCER

ALTHOUGH it is true that the cause of cancer is unknown in most cases, it is equally true that the etiology in certain cases is obvious and that such cancers are therefore preventable. Into the latter class fall the occupational cancers arising in persons as the result of regular and prolonged contact with physical or chemical carcinogenic agents.

Such occupational neoplasms as the soot cancer of chimney sweeps and the cancer of the lung occurring in the Schneeberg miners have long been recognized. That malignant tumors of the bladder occur in workers in the aniline dye industry in the United States was not realized until 1932, and the fact that leukemoid conditions leading to death sometimes fol-

low exposure to benzol even in small amounts was not appreciated until even more recently. Cancer of the lung has been noted among workers in chromate plants and nickel refineries and among asbestos workers. Furthermore, it is said that cancer of the lung kills 75 to 80 per cent of unprotected cobalt workers, and carcinogenic properties have been found in such varied substances as arsenic, tar, crude mineral oil, shale oil, certain aromatic amines and, of course, roentgen rays and rays from radioactive substances.

It has been recommended that the medical profession, as well as employers and employees, be better educated regarding such carcinogenic agents and that special care be taken to guard the worker against them.* Medical supervision of those exposed to carcinogenic agents seems to be a wise step, and it is possible that some form of governmental inspection of industrial plants in which carcinogenic agents are used should be instituted. For example,

an intelligent college graduate who was clearly suffering from early myeloid metaplasia was recently seen by a physician who is particularly cognizant of these industrial hazards. The man categorically denied that benzol was used in the plant in which he worked, yet inspection by the proper state authorities a few days later showed that the plant reeked with benzol and that no precautions were being taken. Such conditions should not exist.

In connection with all occupational cancers it should be remembered that many years of exposure to a given carcinogenic agent may elapse before the malignant neoplasm makes itself manifest, and this very fact is likely to make both the employee and the employer lax in the matter of precautions taken. One should also remember that there are many individual variations in

the reactions of those exposed. Thus, in a family of four, all of whom were equally exposed to benzol over an equal period, one member died of myeloid metaplasia, one of a leukemoid disorder, and one of pancytopenia, the fourth member remained perfectly well, so far as could be ascertained.

Since an increasing number of carcinogenic agents are being found, both in the home and in industry, it behooves all of us to guard against their untoward reactions.

MASSACHUSETTS MEDICAL SOCIETY COMMITTEE ON ETHICS AND DISCIPLINE

Owing to a recent episode reported in the newspapers and involving one of the fellows of the Society, who suffered because of strict adherence to his interpretation of the "Code of Ethics" and the "Oath of Hippocrates," the following observation is offered:

Chapter II, Section 1, of the "Principles of Medical Ethics of the American Medical Association," reads as follows:

eventually developed keloids. Later the defendant told the plaintiff's husband that it was unfortunate, that a thing like that should not have happened and that the staff was going to take steps to correct it, and that apparently it had been caused by the solution's having been allowed to stay on the mat, thus exposing the skin, for too long a period. There was testimony by an expert called by the defendant that the burns were due to friction and pressure, that the use of Scott's solution was accepted obstetric practice and that the plaintiff's injuries were unavoidable.

The trial judge directed a verdict for the defendant on the ground that there was no evidence from which the jury could find that the defendant had been negligent. On appeal the Supreme Judicial Court said in part:

The jury could have found, in accordance with the defendant's admission, that the plaintiff's injuries were due to negligence, that there was no negligence on the part of the plaintiff or of any one other than the defendant, that, by the process of elimination, this negligence was that of the defendant. It is likewise no answer to say that the admissions were merely statements of regret, sympathy and benevolence evoked by human suffering.

The court ruled that the case should have gone to the jury, and the trial judge having directed a verdict for the defendant, a new trial was granted (*Woronka v S—*, Mass Adv Sh [1946] 1207).

CORRESPONDENCE

NEED FOR DIPHTHERIA IMMUNIZATION

To the Editor The number of cases of diphtheria in the City of Boston has continued to increase steadily. The Boston Health Department is making every effort through the press, radio and personal contact to notify all who are charged with the care of children that the number of cases is mounting and is alarmingly high and that immediate action must be taken to control the disease.

In the six years preceding 1946, there were 179 cases, with 10 deaths. In 1946, the corresponding numbers were 157 and 10. So far this year, 66 cases of diphtheria have developed in Boston. This is by far the greatest number of cases that has occurred in any two months during the last fifteen years. It indicates a trend in diphtheria that calls for an aggressive immunization program throughout the city.

This month, a city-wide campaign for diphtheria immunization is being conducted in Boston. Practicing physicians are urged to emphasize the need for diphtheria immunization and booster doses. The Boston Health Department is advocating that all children be taken to their own physicians or, where this is not practical, to the various clinics provided by the Health Department and by school authorities.

Studies indicate that children who have had original inoculations against diphtheria should be furnished booster doses of toxoid at intervals. The Boston Health Department in its clinics uses 0.5 cc of the toxoid supplied by the Massachusetts Department of Public Health, injected subcutaneously. This toxoid is available free of charge at all City of Boston culture stations.

BOOK REVIEWS

The Extremities By Daniel P. Quiring, Ph.D., Beatrice A. Boyle, Erna L. Boroush, M.A., and Bernardine Lufkin, A.B. 8°, cloth, 117 pp., with 105 illustrations. Philadelphia: Lea and Febiger, 1945. \$2.75.

The simple line drawings of the origin, insertion, nerve and blood supply of the muscles of the extremities presented in this volume should be of great service to students and surgeons alike. It seems to the reviewer regrettable that the references are to Gray and Cunningham only, with none to the excellent textbook by Morris. This book is a product of the joint efforts of earnest students at the Cleveland Clinic Foundation. The extensive experience of the authors should serve well the needs of those interested in the functional principle of muscle action.

Physical Chemistry of Cells and Tissues By Rudolf Hober, M.D., J. B. Bateman, Ph.D., David R. Goddard, Ph.D., and Wallace O. Fenn, Ph.D. 8°, cloth, 676 pp. Philadelphia: Blakiston Company, 1945. \$9.00.

This is an extremely interesting and instructive book whose contents convincingly prove that physiology is deeply anchored in physical chemistry. The volume is arranged in sections as follows: selective principles of physical chemistry, large molecules, their physicochemical properties and their architectural and functional significance in living matter, introductory remarks concerning the architecture of protoplasm, the surface of the protoplast, its properties and its architecture, influence of some extracellular factors on cellular activity, the respiration of cells and tissues, contractility, and passive penetration and activity transfer in animal and plant tissues.

The volume has an excellent index of authors and subjects. Each chapter of each section is documented by excellent references. This should be a most useful book for physicians, chemists and physiologists.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

The Vitamins in Medicine By Franklin Bicknell, D.M., M.R.C.P., and Frederick Prescott, M.Sc., Ph.D., A.R.I.C., M.R.C.S., clinical research director, Wellcome Foundation, London. Second edition, revised and enlarged. 8°, cloth, 916 pp., with 208 illustrations. New York: Grune and Stratton, 1946. \$12.00.

This new edition of an English book has been revised by the rewriting and expansion of the chapters on the vitamin B complex and riboflavin. The other chapters have been brought up to date with the advances in knowledge of the vitamins. A new chapter has been added on the essential unsaturated fat-soluble acids (vitamin F) and minor fat-soluble vitamins. The references to the literature have been increased to four thousand five hundred, and the number of illustrations almost doubled. The printing is excellent, with a good type on good paper. A comprehensive subject index concludes the volume. This treatise should prove valuable as a reference source.

The Modern Attack on Tuberculosis By Henry D. Chadwick, M.D., and Alton S. Pope, M.D., deputy commissioner of public health, and director of the Division of Tuberculosis, Commonwealth of Massachusetts. Revised edition. 8°, cloth, 134 pp. New York: Commonwealth Fund, 1946. \$1.00.

This monograph was first published in 1942 and reprinted twice previous to this edition, which has been revised in the light of recent developments in administrative practice and in the technique of case finding and control. New material has been added, and some sections expanded, including photofluorography, the role of mass x-ray examination in industry and other population groups, with emphasis on the

ent role of an organized follow-up system, the financial aspects of hospitalization, rehabilitation, chemotherapy and the federal case-finding program. The volume is recommended for all persons interested in the tuberculosis problem in public health.

BC of Medical Treatment By E. Noble Chamberlain, M.D., M.Sc., F.R.C.P., lecturer in medicine, University of Liverpool, physician to outpatients, Royal Infirmary, Liverpool, and visiting physician, Smithtown Road Hospital. 12th edn, 206 pp. New York: Oxford University Press, 1946. \$3.00.

This small manual is designed for the general practitioner. A quick reference to the therapy of the ordinary diseases. The subject matter is arranged alphabetically, and a number of symptoms, such as pain and insomnia, have been included with the diseases. The book concludes with a fifty-eight-page chapter on diet by Miss Rose Simmonds, which includes any special diet sheets and tables.

Immunological Nonreaginic Food-Allergy By Arthur F. Coca, M.D., medical director, Lederle Laboratories. Second edition, 8th, cloth, 191 pp., with 28 tables. Springfield, Illinois: Charles C. Thomas, 1945. \$3.75.

The author presents in this monograph a method for the diagnosis and treatment of the relatively large groups of allergic diseases, such as migraine, urticaria, gastrointestinal disorders, neuralgias and other conditions hitherto unrecognized as allergic, in which the usual cutaneous tests almost invariably fail. Under the term "idioblastic allergy" are discussed the various aspects of food allergy. The concluding chapters are devoted to a discussion of the inheritance of food allergy, its relation to hypertension, its role in the causation of the common cold and its incidence in cases of cancer of the breast.

The Early Diagnosis of the Acute Abdomen By Zachary Lope, M.D., M.S. (Lond.), F.R.C.S. (Eng.), surgeon to St. Mary's Hospital, Paddington, and senior surgeon to Bellingroth Hospital, Wandsworth Common. Ninth edition, 8th, cloth, 262 pp., with 38 illustrations. New York: Oxford University Press, 1946. \$3.75.

The number of editions of this small manual, first published in 1921, speaks well for its popularity and soundness. This new edition contains only a few minor alterations and additions, but it should find a place in the libraries of all physicians and surgeons.

Psychological Medicine: A short introduction to psychiatry. With an appendix, "Psychiatry Associated with War Conditions." By Desmond Curran, M.B., F.R.C.P., D.P.M., psychiatrist and lecturer in psychologic medicine, St. George's Hospital, and Eric Guttman, M.D., M.R.C.P., neuro-psychiatric specialist, Emergency Medical Service. With a foreword by J. J. Conybeare, M.C., D.M. (Oxon.), F.R.C.P., physician to Guy's Hospital, London. Second edition, 8th, cloth, 246 pp., with 20 illustrations. Baltimore: Williams and Wilkins Company, 1945. \$3.50.

The authors have taken advantage of the need for a new edition of their manual to make an extensive revision of their text. A number of sections and chapters have been rewritten and enlarged. The principal changes are in the sections on constitutional factors, psychopathic personalities and the affective and hysterical syndromes. A chapter has been devoted to the obsessional states, and a brief discussion of psychomatic medicine has been included in the text. A short reading list concludes the volume.

Doctors East, Doctors West: An American physician's life in China. By Edward H. Hume, M.D., 8th, cloth, 278 pp. New York: W. W. Norton and Company, Incorporated, 1946. \$3.00.

Dr. Hume has written an interesting popular narrative of his twenty-five years' work in China. A graduate of Johns Hopkins University, stationed in India as an officer of the United States Public Health Service, he was persuaded by the Yale University Mission to go to Changsha, Hunan Province, in 1905, to establish a modern hospital and medical school. His work ended with the turning over of the hospital to the Chinese government in 1930. The story is valuable for the light it throws on medical practice and popular medical beliefs in China of the old days.

Journal of Gerontology: To add life to years, not just years to life. Volume I, 1946. 4th. Springfield, Illinois: Charles C. Thomas, 1946. Quarterly two parts. \$6.00 a year for both parts, \$3.00 a year for the nontechnical supplement.

This new journal on old age, its physiology, hygiene and diseases, the organ of the Gerontological Society, is a welcome addition to the field of special periodicals. The number of outstanding authorities comprising its editorial staff speaks well for its high standard of quality. The numbers are issued quarterly in two parts, technical and nontechnical. Each article in the former has summaries in English, French, Spanish and Russian. The nontechnical supplement is published for the general public and is written for the average reader who desires information on the subject. It contains abstracts of all the articles published in the technical part, rewritten in plain nontechnical language. It also contains discussions of current economic or social problems of the aged.

Advancing Fronts in Chemistry: A series of lectures sponsored by Wayne University under the direction of Neil E. Gordon, chairman, Department of Chemistry. Volume II: *Chemotherapy*. Edited by Wendell H. Powers, assistant professor of chemistry. 8th, cloth, 156 pp., with illustrations. New York: Reinhold Publishing Corporation, 1946. \$3.25.

This series of lectures discusses the following subjects: chemotherapy in experimental tuberculosis, synthetic antispasmodics, chemistry of the sulfonamides, the antimalarial problem, organometabolic compounds and the chemotherapy of parasitic diseases. Each lecture is well documented, with pertinent references to the literature. This volume is recommended for all medical-reference collections.

The Surgical Technic of Abdominal Operations. By Julius L. Spivack, M.D., LL.D., associate professor of surgery, University of Illinois College of Medicine, senior attending surgeon, Columbia Memorial Hospital, Chicago, and attending surgeon, Oak Forest Infirmary. Fourth edition, revised 8th, cloth, 710 pp., with 682 illustrations. Springfield, Illinois: Charles C. Thomas, 1946. \$10.00.

The first edition of this standard work was published in 1936, and the necessity for this fourth edition attests its popularity and soundness. The text has been revised by the elimination of some material and by the addition of new material. The type has been entirely reset. Selected bibliographies are appended to each chapter, and short historical sketches precede the discussion of each operation. The illustrations are clear and well executed. The book should prove valuable to surgeons and should be in all hospital and medical libraries.

NOTICES

NEW ENGLAND HEART ASSOCIATION

A meeting of the New England Heart Association will be held at Boston University School of Medicine auditorium, 78 East Concord Street, Boston, on Monday, March 31, at 8.15 p.m.

PROGRAM

A Note on Catheterization of the Coronary Sinus in Man and the Oxygen Content of Blood Obtained Therefrom. Drs. James W. Culbertson, Meyer H. Halperin and Robert W. Wilkins.

An Accurate Venographic Technic for the Study of Thromboembolic Disease of the Lower Extremities. Dr. George Mixer, Jr.

The Effects of Local Compression on Blood Flow in the Extremities of Man. Drs. Meyer H. Halperin, Carl K. Friedland and Robert W. Wilkins.

Adrenal Tumors and Hypertension. Drs. John B. Graham and Reginald H. Smithwick.

The Ventricular Gradient in Hypertension. Drs. Norman H. Boyer and William L. Hewitt.

Early Experiences with Total Thoracic Sympathectomy in Hypertensive Patients with Coronary Heart Disease and Angina Pectoris. Drs. Dera Kinsey and Reginald H. Smithwick.

The Effects of Sympathectomy on Certain Vasopressor Responses in Hypertensive Patients. Drs. Robert W. Wilkins and James W. Culbertson.

BOSTON CITY HOSPITAL HOUSE OFFICERS' ASSOCIATION

The April 8 lecture of the Tuesday evening lecture series of the House Officers' Association of the Boston City Hospital will be held in the new Cheever Amphitheater, Dowling Building, at 7 00 Dr Wilder Penfield, director of the Montreal Neurological Institute, will speak on the subject, "Classification and Differential Diagnosis of the Epilepsies," which will be followed by a discussion by Dr William G Lennox

GREATER BOSTON MEDICAL SOCIETY

A meeting of the Greater Boston Medical Society will be held in the auditorium of the Beth Israel Hospital on Tuesday, April 1, at 8 15 p m Dr Philip E Meltzer will speak on the subject "Deafness Its management and recent advances in therapy"

AMERICAN COLLEGE OF SURGEONS

The sectional meeting of the American College of Surgeons, embracing the entire northeastern region of the United States, will open on Friday morning, March 28, at 8 30, and continue through Saturday afternoon, March 29, at the Providence-Biltmore Hotel, Providence Surgeons, members of the medical profession at large, medical students and hospital representatives from this area are invited to attend the sessions, which will begin each morning with the showing of medical motion pictures, followed by separate sessions for the medical and hospital delegates

The scientific session for the first morning will include the following talks "Surgery of Malignant Growths in the Neck," Dr William F MacFee of New York City, "Advances in Anesthesia," Dr Ralph M Tovell, of Hartford, "Surgery of Carcinoma of the Bladder," Dr Samuel N Vose, of Boston, and "Vascular Surgery," Dr Harris B Shumacker, Jr, of New Haven Luncheons for physicians, surgeons and hospital representatives, followed by a discussion of the subjects covered at the morning sessions, will be held on both days

Two panel discussions will feature the scientific sessions on the first afternoon The first, on fractures, will be conducted by Dr Robert M Yergason, of Hartford, with Dr Mather Cleveland, of New York City, and other prominent authorities serving as collaborators The other panel will be on intestinal obstruction and will be conducted by Dr Arthur W Allen, of Boston

A dinner will be held on the evening of the first day, followed by a premiere showing of a medical motion picture now under production and concluding with a reception

The talks at the scientific session on the second morning will be as follows "Use of Antibiotics in Surgical Practice," Dr Frank L Meleney, of New York City, "Surgery of Malignant Growths of the Neck," Dr Francis D Moore, of Boston, "Treatment of Portal Hypertension," Dr Arthur H Blake-more, of New York City, and "Management of Cancer of the Breast," Dr Frank E Adair, of New York City

The scientific-session program for the second afternoon will consist of panel discussions on postoperative care and on carcinoma of the colon The moderator of the first panel will be Dr John H Mulholland, of New York City, with Dr James B Blodgett, of Boston, Dr Bliss B Clark, of New Britain, and Dr E A Rovenstine, of New York City, as collaborators The moderator of the second panel will be Dr Samuel C Harvey, of New Haven, and the collaborators, Drs Arthur W Allen and Richard B Cattell, of Boston

INDUSTRIAL HEALTH MEETINGS

A conclave of combined professional personnel in industrial health work will take place at the Hotel Statler, Buffalo, New York, April 26 through May 4 These meetings will represent the thirty-second annual gathering of the American Association of Industrial Physicians and Surgeons, the ninth annual conference of the American Conference of Governmental Industrial Hygienists, the eighth annual meeting of the American Industrial Hygiene Association, the fifth annual conference of the American Association of Industrial Nurses and the fourth annual meeting of the American Association of Industrial Dentists

The sessions will be replete with many new subjects of interest, including the following round-table discussions for physicians and nurses, a symposium on new problems in the developments of industrial hygiene, a discussion of state codes and industrial-hygiene administration, conferences on environmental control, clinics on fractures and traumatic surgery

with a symposium on back problems, hazards incident to use of the atomic bomb, tracer chemistry in toxicology research, progress in the teaching of industrial medicine in American medical schools, a panel discussion on new preventive measures in industry, and a panel discussion on the education of the nurse in industry Prominent speakers on important subjects will be featured at dinner sessions and other events, such as the Cummings Memorial Lecture and the presentation of the Knudsen Award for the most outstanding contribution to industrial medicine during the past year

Also available at this meeting will be the opportunity to inspect and study a splendid group of scientific and technical exhibits, with the most recent developments and medical department accessories

Further details and a copy of the preliminary program may be secured by writing to Dr Edward C Holmblad, American Association of Industrial Physicians and Surgeons, 28 East Jackson Blvd., Chicago 4 All hotel reservations are made by the Housing Bureau, Buffalo Convention and Tourism Bureau, Incorporated, 602 Genesee Building, Buffalo, New York

AMERICAN PUBLIC HEALTH ASSOCIATION

The seventy-fifth annual meeting of the American Public Health Association will be held in Atlantic City, October 6-10. The scientific program and the exhibits will emphasize progress in public health during the last seventy-five years. The following related organizations will participate in the meeting: American School Health Association, Association of Maternal and Child Health Directors, Association of Reserve Officers of the United States Public Health Service, Association of State and Territorial Health Officers, Conference of Municipal Public Health Engineers, Conference of Professors of Preventive Medicine, Conference of State and Provincial Public Health Laboratory Directors, Conference of State Directors of Health Education, Conference of State Directors of Public Health Nursing, Conference of State Sanitary Engineers, National Committee of Health Council Executives, and Public Health Cancer Association

THE MEANING OF THE PATIENT TO THE HOSPITAL*

IDA M. CANNON, D. HUM. (HON.)†

BOSTON

THOSE of us to whom the old Ether Dome and its furnishings are familiar, need little imagination to picture the scene just a hundred years ago today, when the first public demonstration of anesthesia for a major surgical operation took place. From all descriptions that I have seen, the focus of attention was on the great surgeon, in his frock coat, who dared accept responsibility for operating under untried conditions, on Morton, the dentist, who produced the mysterious stuff, or on the skeptics in the amphitheater. The atmosphere must have been charged as courage and determination met incredulity and suspended ridicule. What must have been the emotions of Gilbert Abbott, the patient, who participated so vitally in this adventure, which happily we can celebrate today? We know little of Gilbert Abbott besides the fact that he came to the hospital for treatment of a tumor of the jaw. But we can readily imagine him as a patient in the old Bulfinch ward and, on the fateful day, as being taken up the stairs to the operating room and placed on a plush operating table.

I suspect that Abbott, like most surgical patients since his time, experienced fear as he faced the oblivion of anesthesia. That he had courage we cannot question. His fortitude, like that of Dr. Warren, was a manifestation of character. But there was a difference, I believe, in the sources of their courage. Dr. Warren's bravery may well have been rooted in confidence in his own mature judgment and a willingness to risk ridicule for the sake of what success might mean to humanity in the future. The patient's courage, doubtless, was based on his faith in the surgeon who had cared for him and the hospital to which he had come for relief. Confidence of this order, which has been a large factor in making the Massachusetts General Hospital what it is today, is the greatest asset a hospital can have. It is not casually or easily earned. It is bred and maintained through consistent high quality of daily

service. Responsibility for holding it rests with everyone who has contact with patients. If standards of service are lowered, the trust of the patients and the public is shaken and may wither away. Confidence in this hospital's devotion to the primary purpose of care of patients not only has been the chief source of patients but also has done much in making possible the maintenance of the other purposes—namely, teaching and clinical research. We in social service have as our special concern the meaning of sickness and hospital experience to the patient. This gives us an opportunity to see the hospital rather objectively in terms of the layman, who is the patient. It also lets us see something of what the patient means to the hospital. I propose to test this theme in terms of the threefold purpose of this hospital—care of patients, teaching and research—and to suggest how these purposes give relevance to the growing social responsibilities of this great institution.

The needs of the sick were the reason why the hospital came into existence. Such obvious facts have a way of becoming dulled as we live with them. It is well to refresh them occasionally by bringing them into the focus of attention. Vivid descriptions of the neglect of the sick, as presented by the Rev. Mr. Bartlett and Drs. Warren and Jackson, brought forth generous gifts that made possible the construction of the Bulfinch Building. The dire state of the sick inmates of the almshouse evidently gave good Mr. Bartlett, the chaplain, sleepless nights, for it was he who stirred the "number of respectable gentlemen" to join with Dr. Warren and Dr. Jackson in the historic appeal to Boston citizens that is found in Bowditch's history of the hospital. This volume, which is one of my treasured possessions, is a dull book. But for a social worker, a few of its four hundred and forty-two pages are of extraordinary interest. Perusal of the Warren-Jackson letter gives an illuminating picture of the social conditions of Boston in those days. We note, on the one hand, the "worthy" citizens who considered themselves, in their affluence, as "treasurers of

THE MEANING OF THE PATIENT TO THE HOSPITAL*

IDA M. CANNON, D. HUM. (HON.)†

BOSTON

THOSE of us to whom the old Ether Dome and its furnishings are familiar, need little imagination to picture the scene just a hundred years ago today, when the first public demonstration of anesthesia for a major surgical operation took place. From all descriptions that I have seen, the focus of attention was on the great surgeon, in his frock coat, who dared accept responsibility for operating under untold conditions, on Morton, the dentist, who produced the mysterious stuff, or on the skeptics in the amphitheater. The atmosphere must have been charged as courage and determination met incredulity and suspended ridicule. What must have been the emotions of Gilbert Abbott, the patient, who participated so vitally in this adventure, which happily we can celebrate today? We know little of Gilbert Abbott besides the fact that he came to the hospital for treatment of a tumor of the jaw. But we can readily imagine him as a patient in the old Bulfinch ward and, on the fateful day, as being taken up the stairs to the operating room and placed on a plush operating table.

I suspect that Abbott, like most surgical patients since his time, experienced fear as he faced the oblivion of anesthesia. That he had courage we cannot question. His fortitude, like that of Dr. Warren, was a manifestation of character. But there was a difference, I believe, in the sources of their courage. Dr. Warren's bravery may well have been rooted in confidence in his own mature judgment and a willingness to risk ridicule for the sake of what success might mean to humanity in the future. The patient's courage, doubtless, was based on his faith in the surgeon who had cared for him and the hospital to which he had come for relief. Confidence of this order, which has been a large factor in making the Massachusetts General Hospital what it is today, is the greatest asset a hospital can have. It is not casually or easily earned. It is bred and maintained through consistent high quality of daily

service. Responsibility for holding it rests with everyone who has contact with patients. If standards of service are lowered, the trust of the patients and the public is shaken and may wither away. Confidence in this hospital's devotion to the primary purpose of care of patients not only has been the chief source of patients but also has done much in making possible the maintenance of the other purposes—namely, teaching and clinical research. We in social service have as our special concern the meaning of sickness and hospital experience to the patient. This gives us an opportunity to see the hospital rather objectively in terms of the layman, who is the patient. It also lets us see some of the old purpose of this hospital—care of patients, teaching and research—and to suggest how these purposes give relevance to the growing social responsibility of this great institution.

The needs of the sick were the reason why the hospital came into existence. Such obvious facts may have a way of becoming dulled as we live with them. It is well to refresh them occasionally by bringing them into the focus of attention. Vivid descriptions of the neglect of the sick, as presented by the Rev. Mr. Bartlett and Drs. Warren and Jackson, brought forth generous gifts that made possible the construction of the Bulfinch Building. The dire state of the sick inmates of the almshouse evidently gave good Mr. Bartlett, the chaplain, sleepless nights for it was he who stirred the "number of respectable gentlemen" to join with Dr. Warren and Dr. Jackson in the historic appeal to Boston citizens that is found in Bowditch's history of the hospital. This volume, which is one of my treasured possessions, is a dull book. But for a social worker, a few of its four hundred and forty-two pages are of extraordinary interest. Perusal of the Warren-Jackson letter gives an illuminating picture of the social conditions of Boston in those days. We note, on the one hand, the "worthy" citizens who considered themselves, in their affluence, as "treasurers of

*Presented at a symposium "The Hospital in the Community" held during the Ether Day Centenary of the Massachusetts General Hospital, Boston, October 16, 1946.

†Formerly, chief of Social Service, Massachusetts General Hospital.

God's bounty," with privileges of "indulgences in the true luxury of wealth, the pleasures of charity"—in contrast to the wretched poor in whose behalf the hospital was established. A hospital was frankly recognized as secondary to a good home for the care of the sick. But the insane presented difficulties even for a good home. In one of Mr Bartlett's early letters, he writes of their plight in terms to suggest a tragedy that might befall anyone. Referring to his experience with insane patients, he writes, "Several persons of respectability seized suddenly and brought to the almshouse were put in cells. Among them Capt Jones was put in a straight jacket." In those seafaring days this suggested a possible fate of our common humanity.

Again, in the Warren-Jackson letter, the housing conditions of the time are revealed. We read of the prospective patient who lived "in a garret or cellar, without light or due ventilation or open to the storms of inclement weather." There is no suggestion of a possible relation of social conditions and ill health. But we recognize an awakening of a humanitarian sense of responsibility for succoring those in trouble. Democracy was stirring, and from those beginnings, the hospital as a social institution has played an increasingly important role in our civilization. It has responded to the basic human needs more fully than any other of our institutions, since, with the growth and development of scientific medicine, the sick of all economic groups and in increasing numbers have turned to our hospitals for care.

The medical profession depends on lessons learned from the hard school of experience to improve its practice. It is a venture to say that this principle is not so truly characteristic of any other profession. Medicine, in its concern with questions of life and death, takes seriously the results of practice and builds up better methods as it looks frankly at success and failure.

Richard Cabot, in his early days as a clinic physician, confessed his failure to give adequate care to his patients. Scientific medicine as then organized and practiced in the outpatient department was lacking in many features essential for thorough examination and treatment. Dr Cabot gives a vivid description of his morning in the clinic in his *Foregrounds and Backgrounds in the Care of the Sick*. With the true sense of the artist that he was, he protests that the clinical picture "will run into confusion and distortion" unless the physician "backs his foreground view with the vista of the distant, the past and the future, the background of the community out of which this individual has emerged and to which he belongs." Again, he writes "Science without humanity becomes arid and finally discouraged. Humanity without science becomes scrappy and shallow." He puts these tests to himself as he faces the patient in his clinic.

Am I seeing the actual facts, the ever-new and unique facts, the crying and immediate needs as they come before me? Am I tracing out as far and as deep as I can the full bearing, the true lesson, the unseen spirit of this moment, this situation, this calamity, this illness? Am I using my eyes and ears, my sympathies and my imagination, as hard as I can? Am I searching for the deepest meaning, the widest bearing, the furthest connection of these facts?

Surely Dr Cabot realized that such comprehension and understanding were impossible for anyone certainly for the physician in the midst and under the pressures of a busy clinic—and that they could be approached only by teamwork of several specialists. But he threw a light on the still remote goal for all who participate in the care of patients. As a first step, the feeble beginnings of social service were initiated. The steady growth of this new adjunct of medicine is due to the soundness of Dr Cabot's concept that this special service was essential to the patient's best care. We learned gradually what the profession of social work might contribute through close and disciplinary co-operation with scientifically trained men. And we learned much from the patients themselves. Richard Cabot became an ardent advocate of case teaching in medicine. As we know, he carried this over into his clinicopathological conferences, which were characterized by frank, eager discussion free from any hampering assumptions of infallibility, since the group, teachers and students, analyzed failure as well as success in diagnosis and treatment.

Our tuberculous patients have taught us much about our public-health responsibilities in the course of planning their care. Drs Arthur Cabot and John Hawes, both of the Massachusetts General Hospital staff, were chairman and secretary of the first State Commission on Tuberculosis. When urging the building of the state sanatoriums, they called on us to appear at legislative hearings to describe the circumstances in which our tuberculous patients were having to be cared for at home, daily exposing other members of the family to infection. Similar testimony has been sought for the promotion of state care of patients with venereal disease and cancer.

Confidence of the patient has a significant bearing on the teaching function of the hospital. In my years of experience at the Massachusetts General Hospital, I have learned how closely related are good care of patients and good clinical teaching. It is a satisfaction to be able to assure, with conviction, prospective patients and anxious relatives that the very presence of medical students means that the teachers are holding the care of the sick at a high level. In making this statement it is fitting to pay tribute to the "amenities of ward rounds," as exemplified by Dr Fred Shattuck, a great clinical teacher, and as expressed in word and deed by our Dr Means. Here, surely, is a tradition to cherish.

The statement of the original threefold purpose of the Massachusetts General Hospital is brief and

simple Yet how tremendous has been the elaboration of each of them — care of the patient, teaching and research — through these momentous years! The irreducible minimum in clinical relation characteristic of the early days, that between the patient and the doctor, was soon increased to include “the kind and discreet nurse” I suspect that even today some patients come to the hospital expecting just such simple professional relations in the course of their care But how different is the reality! In the interest of better service, medicine has developed the complicated organization we now recognize as the modern hospital Nursing, as well as medicine, has been elaborated and specialized The rest of us — dietitians, medical social workers, occupational and physical therapists and laboratory technicians — present the patient with a most complicated environment just when simplification in human relations would be most welcome How important it is that this complex organization should run smoothly! That patients submit and in turn seek the beneficence of the hospital is due, I believe, to their confidence that the staff with all its variety holds to the spirit of the primary purpose of the care of patients The multiple teaching program of this hospital, where all these workers have their practical training, testifies to the acceptance of these supplementary services as essential to a high quality of medical care

The patient is the foundation for clinical research Many unknowingly have contributed to medical knowledge And many patients, such as those in Ward 4, have consciously taken part in the advance of medicine Captain Martell's glowing spirit has brought forth many eloquent expressions of appreciation for his generous and selfless offering of his obscure disease for a better understanding of diagnosis and operative procedure for parathyroid tumor The hospital's annual report for 1932 gave a unique and eloquent tribute to the Captain And Dr Means has told his story in a recent issue of the *Harvard Alumni Bulletin* Many hundreds of patients have served as nobly, since the more baffling and less understood symptoms have been earnestly studied in the course of treatment Happily, out of these untold human dramas, has come much merciful help not only to the patients themselves but also to those who come later, for knowledge of the advances in medicine becomes widespread

The hospital ward has always offered what might be called a social laboratory, which if comprehended could have given evidence of the neglected social ills of the community Hospitals have come to play a role in this field only in recent years I have an illustration of a neglected opportunity A patient, Francis Choate, was admitted to our wards in July, 1851 The diagnosis was “necrosis of the jaw in a phosphorus worker” Sixty-one years later the record of this case was used to help promote the passage of the Esch Bill, prohibiting the use of white

phosphorus in the manufacture of matches This is how it happened In 1909, John Andrews, secretary of the American Association for Labor Legislation, came to me to ask if I could help him find early cases of “phossy jaw,” as it was called, which had long been known to be caused by exposure of workers to the processes of match manufacture Mr Andrews, working with Senator Esch, had collected evidence from 150 current cases of this disease He wanted to strengthen his evidence by showing how long this disease had been known but neglected in the United States whereas European countries had long since prohibited the use of white phosphorus in industry As was our habit in such a search, I went to Mrs Myers, who in a few hours produced Francis Choate's record The following is an abstract from the history, as contained in the hospital record of 1851

[The patient] has worked for 14 years on phosphorus in manufacture of matches dipping cards of matches into phosphorus The room in which he worked would be filled with the fumes of it and he used to sit with his head over the vessel from which it came He says not many can stand the work because of bronchial irritation which it excites Usually shift workers [The] teeth have dropped out Half a dozen fistulous openings along the jaw Masses of dead bone protrude into mouth from toothless jaw

The patient was discharged on July 26 and advised to go to the country and return at a later date He returned in November, and filed away in Treadwell vault is the final record, a vivid description of his wretched state, his death and the autopsy Shortly before his death the record tells us, “he dozes over the fire,” much to his comfort I trust Little could he realize that many decades later his case, along with overwhelming current statistical evidence, would finally stop what the *Congressional Record* of 1912 designated as “one of the most loathsome diseases of our civilization” In that year, the use of white phosphorus in match manufacture was prohibited, and a patent of a harmless substitute was surrendered for cancellation A method, safe and effective, was established for use by the men who work in the match industry

In the early days of social service, a sixteen-year-old Russian-Jewish girl was referred to me, with a request that we arrange for payment for a back brace, to correct a lateral scoliosis She had been working for over a year at a machine that called for repeated, frequent shifting of heavy levers from right to left When this was reported to the orthopedist, his comment was “a perfect case of occupational scoliosis,” and he urged her to change her job This advice disturbed the patient, for her earnings in the daytime left her free to go to school in the evening But she did change her job The interest of the Child Labor Committee was enlisted, and the factory inspectors ordered that this machine be run by a male operator thereafter All this was before the passage of the Industrial Accident Law and just before Dr Edsall came to the hospital and de-

God's bounty," with privileges of "indulgences in the true luxury of wealth, the pleasures of charity"—in contrast to the wretched poor in whose behalf the hospital was established. A hospital was frankly recognized as secondary to a good home for the care of the sick. But the insane presented difficulties even for a good home. In one of Mr Bartlett's early letters, he writes of their plight in terms to suggest a tragedy that might befall anyone. Referring to his experience with insane patients, he writes, "Several persons of respectability seized suddenly and brought to the almshouse were put in cells. Among them Capt Jones was put in a straight jacket." In those seafaring days this suggested a possible fate of our common humanity.

Again, in the Warren-Jackson letter, the housing conditions of the time are revealed. We read of the prospective patient who lived "in a garret or cellar, without light or due ventilation or open to the storms of inclement weather." There is no suggestion of a possible relation of social conditions and ill health. But we recognize an awakening of a humanitarian sense of responsibility for succoring those in trouble. Democracy was stirring, and from those beginnings, the hospital as a social institution has played an increasingly important role in our civilization. It has responded to the basic human needs more fully than any other of our institutions, since, with the growth and development of scientific medicine, the sick of all economic groups and in increasing numbers have turned to our hospitals for medical care.

The medical profession depends on lessons learned from the hard school of experience to improve its practice. It is a venture to say that this principle is not so truly characteristic of any other profession. Medicine, in its concern with questions of life and death, takes seriously the results of practice and builds up better methods as it looks frankly at success and failure.

Richard Cabot, in his early days as a clinic physician, confessed his failure to give adequate care to his patients. Scientific medicine as then organized and practiced in the outpatient department was lacking in many features essential for thorough examination and treatment. Dr Cabot gives a vivid description of his morning in the clinic in his *Foregrounds and Backgrounds in the Care of the Sick*. With the true sense of the artist that he was, he protests that the clinical picture "will run into confusion and distortion" unless the physician "backs his foreground view with the vista of the distant, the past and the future, the background of the community out of which this individual has emerged and to which he belongs." Again, he writes "Science without humanity becomes arid and finally discouraged. Humanity without science becomes scrappy and shallow." He puts these tests to himself as he faces the patient in his clinic.

Am I seeing the actual facts, the ever-new and unique facts, the crying and immediate needs as they come before me? Am I tracing out as far and as deep as I can the full bearing, the true lesson, the unseen spirit of this moment, this situation, this calamity, this illness? Am I using my eyes and ears, my sympathies and my imagination, as hard as I can? Am I searching for the deepest meaning, the widest bearing, the furthest connection of these facts?

Surely Dr Cabot realized that such comprehension and understanding were impossible for anyone—certainly for the physician in the midst and under the pressures of a busy clinic—and that they could be approached only by teamwork of several specialists. But he threw a light on the still remote goal for all who participate in the care of patients. As a first step, the feeble beginnings of social service were initiated. The steady growth of this new adjunct of medicine is due to the soundness of Dr Cabot's concept that this special service was essential to the patient's best care. We learned gradually what the profession of social work might contribute through close and disciplinary co-operation with scientifically trained men. And we learned much from the patients themselves. Richard Cabot became an ardent advocate of case teaching in medicine. As we know, he carried this over into his clinicopathological conferences, which were characterized by frank, eager discussion free from any hampering assumptions of infallibility, since the group, teachers and students, analyzed failure as well as success in diagnosis and treatment.

Our tuberculous patients have taught us much about our public-health responsibilities in the course of planning their care. Drs Arthur Cabot and John Hawes, both of the Massachusetts General Hospital staff, were chairman and secretary of the first State Commission on Tuberculosis. When urging the building of the state sanatoriums, they called on us to appear at legislative hearings to describe the circumstances in which our tuberculous patients were having to be cared for at home, daily exposing other members of the family to infection. Similar testimony has been sought for the promotion of state care of patients with venereal disease and cancer.

Confidence of the patient has a significant bearing on the teaching function of the hospital. In my years of experience at the Massachusetts General Hospital, I have learned how closely related are good care of patients and good clinical teaching. It is a satisfaction to be able to assure, with conviction, prospective patients and anxious relatives that the very presence of medical students means that the teachers are holding the care of the sick at a high level. In making this statement it is fitting to pay tribute to the "amenities of ward rounds," as exemplified by Dr Fred Shattuck, a great clinical teacher, and as expressed in word and deed by our Dr Means. Here, surely, is a tradition to cherish.

The statement of the original threefold purpose of the Massachusetts General Hospital is brief and

James Homer Wright on blood platelets and actinomycosis and the development of his blood stain, the classic studies of Aub on lead poisoning, leading on to studies by Albright on calcium metabolism, obscure bone diseases and the action of hormones, Bauer's studies of arthritis, the work of Means and his associates on the thyroid gland, the initial use of liver therapy by Minot, Dr Paul D White's development of cardiology, and the calorimetric studies of Dr. Fritz B Talbot. From the procession of skillful surgeons, it would be unfair to choose names, since all contributed something to the advance of aseptic surgery. It is justifiable, perhaps, to note the development of chest surgery by Robinson, Whittemore, Richardson and Churchill and of hip nailing by Smith-Petersen.

The Massachusetts General Hospital has trained over 1650 house pupils, house officers, interns and residents, who have carried the lessons learned here throughout the world and through four wars. Here was established the second school of nursing in the United States, with 3151 graduates forming the largest alumnae group of any nursing school. It was one of the first to provide accommodations for private patients and built the Baker Memorial, the first hospital for people of moderate means, on the basis of the principle of high-quality hospital care at cost and of medical care with limited fees. Thus, this hospital has pioneered in many fields. It has always placed the welfare and interest of the patient first and so has been quick to accept and adopt advances made in other fields. Its associations with Harvard University and the Massachusetts Institute of Technology have helped it to maintain an open mind and to retain a youthful spirit. It has surely developed what Harvey Cushing called the "soul of a hospital." It has been, and still is, all that a great hospital should be. It must and shall be preserved.

The survival of the voluntary hospital in the modern world is mentioned because, as Garrison states, "As we enter the machine age the salient fact about medicine is the trend toward socialization." This suggests increasing participation of government in hospital affairs. Much that follows can apply to all voluntary hospitals but especially to the small group of university-connected hospitals in which teaching and clinical and fundamental research, in addition to the care of patients, are carried on, of which the Massachusetts General Hospital is an example.

The problem of finances is primarily one of income, which is derived from two sources — annual gifts and payment for service rendered, either from patients as individuals or from organizations responsible for their care.

The anticipated deficits of voluntary hospitals, which were founded to provide care regardless of the ability of the patient to pay, have in the past been met through gifts and legacies from philan-

thropic citizens. This hospital has been particularly fortunate in its benefactors and yet it is confronted with annual deficits that threaten to consume its accumulated capital. If it is true to its principles it cannot meet this need solely by raising charges to patients since this would establish the precedent of making only the sick pay for the sick. Yet federal and state tax systems, through income and inheritance taxes, have seriously reduced the number of large individual gifts and legacies. How can they be replaced?

We are passing from a period in which the support of voluntary hospitals was considered to be the philanthropic duty solely of the well-to-do and rich to one in which it is believed that such institutions must be supported by their beneficiaries. Obviously, this means industry and labor, from a corporate standpoint, and employers and employees, from an individual standpoint. It is this conception that has produced so-called "community chests," which are built on the principle of supplementing the larger gifts of a relatively small group of citizens by many smaller donations from all classes. As corporate bodies receiving benefits, industrial concerns must support hospitals. Labor, through its unions, whose members also receive benefits, must now assume a similar share of responsibility. Likewise, as individuals, each worker and each member of management must make his contribution either to the hospital of his choice or to the community chest, from which it may be distributed to all hospitals in the community. If the voluntary hospital is to be retained it must be financially supported by its community.

We are proud of the generosity of Boston's citizens. We are proud of the accomplishments of the Greater Boston Community Fund, but the Fund has been woefully deficient in meeting the financial needs of the voluntary hospitals of Greater Boston. If it desires the continuation of these voluntary hospitals it must do more. The alternative is clear. Hospitals we must have for the care of the sick, for the teaching of doctors, nurses and others and for research. Shall it be a voluntary tax for the support of voluntary hospitals, or shall it be a federal tax for the support of governmental hospitals? In which way will the money go farthest?

A special group of industrial beneficiaries comprises the pharmaceutical manufacturers, which produce hospital supplies. Many are national in scope. The hospitals not only are the largest users of their products but also must be depended on as the laboratories in which new products are finally tested. The manufacturers should support hospital research, and their conception of research should be broad. Grants-in-aid should be made for specific problems, unrestricted gifts for general or fundamental research and, finally, grants for pharmaceutical research and free beds in recognition of the fact that the ultimate goal is the application of the result of the preliminary type of research to the patient. A drug may be

veloped the Industrial Clinic David Edsall had a fine critical sense of the importance of clinical evidence. He encouraged analysis of the patient's work as a regular procedure in history taking as a means of bringing to light possible exposure to industrial poisons, special strains or adverse conditions that might affect the clinical picture. In this way, he often arrived at a more accurate diagnosis. He was also able, at times, with facts in hand, to demonstrate to industrial managers the evil effects of some of their processes on the human organism.

Hospitals have become, rather reluctantly, one of the best indexes of community health. I say reluctantly, for I remember the resistance of the medical profession to comply, at first, with the public-health measures requiring reporting of diseases declared dangerous to public health. It required a major adjustment, since such reporting seemed to run contrary to the sacred tradition to hold information about patients inviolate. The potential patient became the object of preventive medicine and, as such, has drawn the hospital into his service on an ever broadening concept of responsibility. Psychiatry, through its deepening insights and understanding, is bringing to light the more subtle influences of our social and physical ill-health and our well-being.

Dr Harvey Cushing, in his delightful address at the Centenary Celebration, paid tribute to a long

line of doctors, nurses and employees who had created and maintained what he called the "personality of the hospital." We who have belonged to the Massachusetts General Hospital family know what he meant by that phrase. Intangible it is, and yet a reality to us. We sense certain characteristics of the Massachusetts General Hospital that have steadily carried on its traditions through the decades. The personality of this most human of institutions has been consistent but happily not static. It has matured through the years in constant interaction with the community to which it has devoted its beneficence. Clinical medicine and public-health programs are becoming more closely related as medical knowledge is more widely and practically applied. In this broadening sphere the hospital administrator has had to take and will increasingly have to assume leadership. But, as the full measure of social obligation of medical institutions is more clearly comprehended, we shall realize that responsibility rests on all of us — trustees, administrators, all the professional groups and personnel — and on the public to which we look for support. We shall build wisely if we remember that in the future as in the past our primary responsibility is to the patient for whom the hospital exists.

THE VOLUNTARY HOSPITAL — HOW CAN IT SURVIVE IN THE MODERN WORLD?*

NATHANIEL W. FAXON, M.D.†

BOSTON

IN 1811 the citizens of Boston, led by a minister, a physician and a surgeon, established the Massachusetts General Hospital. The McLean Hospital, for patients with mental diseases, was opened in 1818, and the hospital for medical and surgical illnesses in 1821. Thus was sickness divorced from poverty and crime, from the almshouse and the prison.

The first state hospital, the Worcester Lunatic Hospital, was not built until 1830, twelve years after McLean Hospital, the Boston City Hospital was opened in 1864, forty-three years after the Massachusetts General Hospital. Thus did private foresight, initiative and action precede political recognition. What happened in Massachusetts happened elsewhere in the United States. Private philanthropy and private agencies have almost universally pioneered in medical and social needs that, when demonstrated, have often but not always been

accepted in whole or in part by government. Non-profit or, as they are usually designated, "voluntary hospitals" have been the pacemakers that have set the standards and made the advances. In such hospitals lie our hope and our security.

A consideration of what has been accomplished in this institution alone is illuminating: the demonstration of ether as an anesthetic, a boon accepted but scarcely appreciated by you who gather here to celebrate the centenary of this epoch-making event, the discovery of the Y ligament and a new method for reduction of dislocation of the hip, by Dr Bigelow, the recognition of appendicitis, leading to a rational and successful method of operative treatment, by Dr Reginald Fitz, Shattuck's revolutionary treatment of typhoid fever, the establishment of Social Service, by Dr Richard Cabot, the long fight of Amory Codman to awaken interest in and acceptance of end results and the true evaluation of the success of surgical or medical treatment, recognition of the importance of pathology through the erection of one of the first, if not the first, pathological buildings and the work therein of Dr

*Presented at a symposium "The Hospital in the Community," held during the Ether Centenary of the Massachusetts General Hospital, Boston, October 16, 1946.

†Director, Massachusetts General Hospital and Massachusetts Eye and Ear Infirmary.

No third party has yet paid in full all hospital costs, and the deficit has been met by the hospital from income from endowment, gifts of individuals and grants from the Greater Boston Community Chest. Certainly, the contribution of the Massachusetts General Hospital toward the care of patients for whom state and federal agencies are responsible and for cases under the Workmen's Compensation Act is over \$100,000 a year.

What should be the relation of the hospital to these responsible agencies? The problem cannot be solved by a refusal to admit such patients. No hospital worthy of its name can refuse admission to patients in real need of treatment, with critical illness or following accidents, so that such patients will always be found in this hospital.

The argument that the hospital gets more for an indigent patient than it would if the patient alone was responsible and that for industrial accidents the Workmen's Compensation Act assures the hospital of some payment, whereas before the act was passed the hospital often got nothing, is a specious half truth. If government is responsible, should it not assume full responsibility? Should the hospitals subsidize industry and insurance companies? Regardless of what arrangements a hospital makes with individuals, using its own funds to make up deficits, should responsible governmental agencies likewise become beneficiaries of hospital charity? Should a situation be continued by which endowments given for "the care of the sick poor" or "for free beds" and donations to the Community Chest are used to defray expenses of the Department of Public Welfare or the Children's Bureau?

Thus, there are two conflicting ideologies. On the one hand, a hospital asks that government pay the full cost of care for any patient in any hospital, that cost to be determined according to acceptable governmental accounting formulas, on the basis that such a cost is a true reflection of the care given and received, and on the other hand there is the desire of government to obtain care at as low a cost as possible and as a final safeguard, the establishment of a ceiling payment rate, so that it can approximate a maximum budget for hospital care.

The present situation can scarcely endure. New groups are brought under governmental care every few years. Health-insurance legislation, such as that proposed by the Wagner-Murray-Dingell Bill, is before Congress. This would include practically all residents of the United States. It would authorize payment to hospitals of "not less than \$3 nor more than \$6 for each day for hospitalization not in excess of thirty days," for services that cost the Massachusetts General Hospital \$11. Even if this hospital was granted the right to charge patients the difference between the Government payment of \$6 and the cost of care, I doubt whether it could collect, because people would believe that the Government had promised them hospital care at

no cost in return for the wage deductions for health insurance. How could hospitals provide a subsidy of such an amount on all patients?

There are three possible solutions that hospitals continue to make up the difference between the cost of care and governmental payments, which, unless unexpected and unforeseen sources of income appear, is impossible, that hospitals provide less expensive and, therefore, presumably a lower grade of care for governmental beneficiaries — this is repugnant to physicians, hospital administrators and trustees, who have always striven to give medical care of the same quality, regardless of the patient's classification as ward, semi-private or private, the difference in hospital charge representing only a difference in luxury or privacy of hospital accommodations, and, moreover, an argument for the political demagogue is thus presented, and that the Government pay the full charge or cost of care. That the Government is beginning to recognize the justice of this last request is evidenced by the stand taken by certain federal agencies, but it has not been generally accepted by all agencies or by any state departments.

The high cost of hospital care is a frequent criticism of our hospital system, so that a word regarding costs is perhaps appropriate. The costs for each patient a day advanced from \$1 in 1857 to \$11 in 1945. During the same period, however, the current income per capita rose from \$140 in 1857 to \$1037 in 1943. This is nearly the same ratio of increase, so that although a patient had to pay eleven times as much for hospital care, he had a proportional increase in income with which to pay it.

Hospital costs vary to a considerable degree in different institutions. In the voluntary general hospitals of Boston the range is from \$8 to \$11. Costs are highest in teaching hospitals connected with medical schools. They must have extensive "readiness to serve" equipment, such as laboratories of all sorts, x-ray facilities and physical therapy. They must be prepared to receive patients at any hour, with operative personnel available if needed. They receive the most difficult cases. They develop and refine most of the advances in medical care, and pioneering is always expensive. Lastly, there is some expense, difficult to separate from operating costs, chargeable to teaching medical students, interns, residents, nurses, social workers, dietitians, technicians, physical therapists and others, and this is the hospital's contribution to education. Regardless of cost, it is essential that these groups be taught and given practical training. This can only be carried on in a teaching hospital.

On the other hand, hospitals, including teaching hospitals, have been notorious for paying salaries and wages below the level paid for similar work in industry. Longer hours of work are usually required. Hospitals have ever been frugal buyers. It is therefore fair to assume that whatever the cost, it is not

efficient in a test tube but may fail to cure a human being. Only in hospitals safeguarded and controlled by an efficient and watchful staff can the final test be made. *Hospitals deserve the generous support of all pharmaceutical manufacturers.*

So much for financial support through donations.

The second part of the financial problem consists in return for services rendered, which must be divided into services for which individuals are responsible and those for which governmental or other agencies are responsible.

It is generally agreed that private patients should pay cost or even a little more than cost and that semi-private patients should pay full cost. These classes can be dismissed from further consideration, since they create no financial problem.

Hospitals have traditionally set the ward rate and charged individual patients less than the cost of care. Thus, the present ward charge in this area is \$6 a day for board, bed and general service — items that cost the hospital \$8 a day. Extras such as x-ray films, operating room and laboratory fees, usually billed at cost, total approximately \$3, making a daily cost to the hospital of about \$11. Thus, full-pay individual ward patients contribute \$9 for services costing \$11. About 40 per cent do so. Another 30 per cent pay only a part of this cost, whereas the remaining 30 per cent are free patients.

There is at present a divided opinion regarding whether hospitals should continue their traditional policy of setting ward charges lower than cost or whether charge and cost should be synonymous. According to the first method all ward patients are benefited or are, in other words, the recipients of charity, but by the same token, the greater the number of patients cared for, the greater the financial strain on the hospital. There has therefore been a growing inclination on the part of hospital administrators to make charges equal cost, recognizing that fewer people will be able to pay ward charges in full and that larger allowances or remittances will have to be made. The gain would be that all would have a clear idea of what hospital care really costs. Gifts would still be needed to make up the difference between what ward patients would be able to pay and the charges that they would be asked to pay.

Another situation is created when a third party enters into the transaction — for example, the Department of Public Welfare, responsible for the care of an indigent patient, or an insurance company, responsible under the Workmen's Compensation Act for the hospital care of a patient who has met with an industrial accident. In each instance this third party has been made responsible by law, under certain conditions, for hospitalization. The hospital now deals financially with the third party, not with the patient. In itself there is nothing reprehensible in third-party contracts. The trouble occurs when such parties do not meet their financial responsibilities in full. The government has a way

of legally accepting a responsibility and then passing part of the financial burden to hospitals. Agencies frequently profess to be willing to pay the rates charged to individual patients, but to date none has ever done so. There has always been a gap, even when the hospital charge was less than the cost. If charge and cost were synonymous, the discrepancy would be still greater.

During the past year the Massachusetts General Hospital has received patients from the following sources: state and local departments of welfare, responsible for the care of indigents, department beneficiaries under Old Age Assistance and Aid to Dependent Children Acts and those from the Division of the Care of the Blind and the Deaf, the Department of Correction — that is, from state reformatory schools and prisons, state and local departments of health, responsible for the care of patients with contagious disease, including selected cases of tuberculosis for operation and arthritic patients for study and treatment, the Massachusetts Department of Public Health, which is the local administrative body for the federal program for care of crippled children, the United States Public Health Service, which controls genitoinfectious diseases, the Emergency Maternity and Infant Care Program and the Vocational Rehabilitation Plan, and employees coming under the Workmen's Compensation Act, administered by the Industrial Accident Board. This is a formidable, although not complete, list of governmental agencies that, by law, must provide hospital care for their beneficiaries. Each decade sees the addition of new agencies so that the problem now under consideration is increasing.

The admission of patients coming under the jurisdiction of these agencies has resulted in the following financial situation. As pointed out above, it costs the Massachusetts General Hospital a total of \$11 a day for each ward patient. Public welfare and other state agencies pay \$5 a day, which means that the hospital is contributing more for the care of an indigent patient than the responsible governmental agency. In 1945 this cost to the hospital amounted to over \$50,000. The Industrial Accident Board approves hospital charges to insurance companies at the rate of \$4.75 a day, in addition to approximately \$3 for extras, making a total of \$7.75 a day, which means that the hospital is contributing \$3.25 a day for each patient in this category. Yet this is supposed to be an insurance plan supported by industry and not intended to be a charity. In 1945 this cost to the hospital amounted to over \$30,000. The Massachusetts Department of Public Health, administering the federal Program for Crippled Children, the Emergency Maternity and Infant Care Program and the Rehabilitation Program, pays \$8 a day, so that here too, although to a lesser degree, the hospital contributes \$3 a day to the care of patients supposedly provided for by a federal program.

ship devote seven years after graduation from medical school to special training and limited practice. For those who graduated from medical school after January, 1938, a year must be spent as an intern in an acceptable hospital and at least two years as a resident, as a full-time surgical assistant to a qualified surgeon or in an apprenticeship of equivalent value. More recently, the American College of Surgeons has further increased the period of hospital training for candidates who graduated after January 1, 1944, to a minimum of four years of hospital service and graduate study in the basic sciences. More specific is the American Board of Surgery,² which requires that applicants, before they are permitted to stand a written, clinical and laboratory examination, spend a minimum of five years devoted to surgical training after completion of a year of internship.

According to the American Medical Association,³ at the end of 1945 there were 6511 registered hospitals with a total bed capacity of 1,738,944, the actual utilization of beds being 10.6 per 1000 population. Hospital facilities are increasing both in proportion to the population and in actual numbers. The following figures are of significance⁴:

YEAR	BED CAPACITY
1930	1,000,000
1940	1,226,245
1945	1,738,944
1950	2,000,000 (estimated)

Of the 6511 registered hospitals, 4744 were general hospitals, 3066 of these had a capacity of 100 beds or less, 1148, a capacity of 100 to 300 beds, and 530, a capacity of 300 beds or more. The total capacity for the 4744 general hospitals was 922,549 beds. Of the 530 hospitals with a capacity of 300 beds or more, in which the average was about 1150 beds, less than 100 were in medical centers.⁴

In an attempt to determine the number of surgeons required in the future, it is necessary to consider the estimated increase in the total number of hospital beds that will be required during the next few years. From the figures cited above, it can be estimated that by 1950 there will be approximately 2,000,000 hospital beds. Indeed this will create an increase in the number of surgeons that will be required. The Committee on Graduate Training of the American College of Surgeons⁵ reported in 1939 that there were 6288 surgeons in the United States properly qualified and doing most of the surgery. In the same year, 231 hospitals were credited as having adequate facilities for training in surgery. These hospitals provided positions for 1234 surgeons in training. Also in the same year, 541 surgeons completed the training offered by these 231 hospitals, 145 having completed three years or more and 396 less than three years. It is evident, therefore, that only a limited number of this group would be eligible for examination by the American Board of Surgery or recognition by the American College

of Surgeons. In 1945 the American College of Surgeons⁶ reported that there were 249 hospitals in the United States and Canada conducting approved plans of graduate training in general surgery and the specialties. Two hundred and three of these were for general surgery. This information suggests that facilities for training in surgery had not kept pace with the increase in hospital beds. During the war years 1942-1945, however, surgical training was largely curtailed, and it may be expected that by 1950 there will be an increase in the facilities for training in surgery.

If 6300 surgeons were required to fulfill the needs of the country in 1939 and if the statistics are correct that 3 per cent of the total either die or retire from practice each year, it becomes apparent that a much larger number of completely trained surgeons will be required each year from now on. There must be not only replacements but also those to meet the increased demand because of the opening of new hospitals.

There are in the United States 69 approved medical schools, which for the most part make the best training hospitals and set the pace of hospital practice. The clinical sections of these medical schools contribute to the graduate training of the majority of men who are preparing to qualify for one of the boards. At present, the medical centers of the medical schools are the only hospitals that are properly equipped to provide for complete training in surgery including the basic sciences of anatomy, pathology and physiology.

These medical schools and their medical centers, however, are not adequate to provide training for the number of surgeons that are needed. They are specifically lacking in clinical facilities. And at the same time, in the non-medical-school hospitals, there is clinical material that could well be used for training purposes. The young physician who seeks training and has as his objective the requirements of the American Board of Surgery will find competition keen in the medical-school hospitals. If he turns to a nonacademic hospital his training is frequently less desirable because teaching facilities are lacking and in particular opportunities for work in anatomy, physiology and pathology are not available. Of course, some large hospitals compare favorably with those of the medical centers, but by and large this is not true for the majority of hospitals.

The trend to hospital practice and that toward a greater number of hospital beds indicate that there will be a demand for more physicians to be qualified as specialists by the boards. This is particularly true of surgery. If, as pointed out above, the medical schools are limited in the number of men they can train with their clinical facilities and if clinical facilities are available in the non-medical-school hospitals, it is logical to correlate the two so that the specialists that are needed may be trained.

extravagant, that it represents in all instances full value received and that discrepancies in operative costs in various hospitals represent the difference in care demanded by the complexity of the cases treated

The last problem deals with legislation. Voluntary hospitals should be concerned with the growing tendency of legislatures, including Congress, to consider hospitals in the same category as business and to include them in laws passed primarily to control industry. Hospitals should conform to many regulations, such as fire, building and sanitary laws, and should operate in many ways on business principles. But the demands of sickness, the conception of charity and the application of medical ethics make the operation of a hospital something more than a business.

One cannot operate on strictly business principles when one deliberately gives away something at less than cost. Legislation and regulations affecting hospitals should take this into consideration and should be separated from those regulating industry. Hospitals cannot survive a legislative program that, on the one hand, through the Minimum Wage Com-

mission, increases wages and reduces hours of labor, and on the other, by statute or departmental regulations, prohibits governmental agencies from paying full costs for the care of their beneficiaries. Legislation that affects hospitals should be patterned for hospitals, not for industry.

* * *

What has been said at length can be summed up in a few words. The health and death rates of a community are in direct relation to the amount of money intelligently spent on sanitation, preventive medicine, the education of doctors and others engaged in the care of the sick and the support of medical schools and hospitals. If the people of Boston and the United States want good hospitals, they must pay for them. If they want voluntary hospitals, they must support them through individual gifts, through industrial donations, through the requirement that governmental agencies assume their obligations in full and through modification of legislation affecting them. Only in this way can the flower of our hospital system, the pacemaking voluntary hospital, be preserved.

THE POSSIBLE ROLE OF THE COMMUNITY HOSPITAL IN GRADUATE TRAINING IN SURGERY*

FRANK GLENN, M D †

NEW YORK CITY

AMERICAN medicine and surgery have made great strides since ether anesthesia was first employed in Boston a hundred years ago. Hospitals during this century have become more numerous and greatly improved, the present trend being toward caring for an ever-increasing proportion of the population. These hospitals have become one of the important institutions of almost every community throughout the country. The part that they will fulfill in the health of the Nation in the future, it seems, will be even greater. The possible role of the community hospital in surgical training is but one aspect of the question.

In presenting this subject for discussion, I shall elaborate briefly on the community hospital as a unit and on the distribution of hospitals over the country. The established standards of surgical training are reviewed, and the need for extending surgical training in the non-medical-center hospitals is stated. The possible role of the community hospital in this surgical training is based on the premise that better surgical care is desirable. A plan is suggested for surgical training in these hospitals that, it is believed, will contribute to that ultimate goal.

The term "community hospital" is an elastic one. It may include the small hospital of a few beds at one extreme and the large city hospital of a thousand beds or more at the other. The hospital under discussion, however, is one in a town of 10,000 to 20,000 population and provides hospital care for 40,000 to 80,000 people within a radius of several miles. Such a hospital ordinarily has from 150 to 400 beds. It is an institution of first importance to everyone in the community and is operated by a lay and professional board representative of the people. A significant section of any hospital is the surgical service. The surgical therapy accorded the patients depends on the training and experience of the surgeon. Surgeons of the community hospitals should have breadth and firmness of foundation in their training because their responsibilities are great.

For a hundred and fifty years in this country surgical training was for the most part informal and vague. Over the past five decades various patterns that one might follow to become a surgeon have evolved. In the last twenty years these have become more distinct, with the result that surgical training has been defined and standards established by the American College of Surgeons and the American Board of Surgery. The American College of Surgeons¹ requires that candidates for member-

†Associate professor of clinical surgery, Cornell University Medical College; associate attending surgeon, New York Hospital.

the non-medical-center institution, by co-operation, can contribute a great step in the evolution of American medicine. Together, they can provide for the medical-school graduate an opportunity to fulfill the requirements of such boards as he may wish to qualify for.

The direct plan of training will not only provide an opportunity to develop but also create a relation between the physicians in the local hospitals and in the medical centers. Those from the former may attend meetings in the latter, using their additional library facilities and being afforded a channel for seeking aid in solving their more difficult clinical problems. Furthermore, the members of the staffs of the medical centers might be drawn on to speak on subjects of special interest. In turn, there would also be opportunities for those who had basic instruction in the centers to extend their training in the local hospitals and at the same time to become acquainted with practice. For it is indeed a difficult step from work in a large hospital to the actual practice of surgery in a community.

There is a strong trend for federal and state governments to assume control of hospitals, particularly in the building and maintenance of new hospitals. This is, of course, the product of a philosophy of government that seeks to regiment more and more the activities of its citizens. It includes the limitation of incomes and a so-called "redistribution of wealth." We may not as individuals agree with this program, but we are confronted with the problems it presents to the medical profession. One of these problems is financing the cost of training in the specialties. As you are doubtless aware, one of the most recent and far-reaching legislations, the Hospital Survey and Construction Act, was passed by the Seventy-ninth Congress of the United States and signed by the President during the early part of August, 1946.⁷ The stated purpose of the act is to assist the states as follows:

to inventory the existing hospitals, to survey the need for construction of hospitals, and to develop programs for construction of such public and other non-profit hospitals as will, in conjunction with existing facilities, afford the necessary physical facilities for furnishing adequate hospital, clinic, and similar services to all their people, and to construct public and other non-profit hospitals in accordance with such programs.

The emphasis in the building of the community hospitals has been on the physical plant and equipment. This is important, but more important is the hospital staff, which must be continually improved. The quality of the work done by a staff is dependent on the training of its members. At present, in many hospitals throughout the country, the surgery is done by men who were trained the hard way — by having a minimal amount of formal instruction. This method has produced many good surgeons and many poor ones. The community needs to contribute to the cost of the staff as well as to the building and its equipment. There is needed

a subsidy for paying certain members of the senior staff for carrying out a training program, in addition to providing the surgeon in training a sufficient income so that he can maintain a social position equal to that of his peers in other professions, such as law and engineering.

He who embarks on a career of surgery is confronted with a long period of training after graduation from medical school. Heretofore, the surgeon after an equally long period of residency or apprenticeship with little or no income could expect and have over a short earning period compensation that would enable him to equal the income of his medical confreres by the time he had reached the age when he could no longer work. Thus, his family, although often an addition of his later life, had security and provision for education. Today, taxes and the trend of fees make the annual net income of the surgeon during his most active periods of practice so limited that he cannot set aside an appreciable saving that will compensate for the long lean years of preparation or provide for his old age. If medical-school graduates are to continue to embark on surgical careers with an eye to their immediate and future livelihood, they should receive a reasonable subsidy during this training period. The cost should be borne by the hospital, the community or the state. If incomes are to be limited, a subsidy should be available when long years of preparation are required. Surgery, more than other divisions of medicine, demands intensive and prolonged training. The past generation has seen those who are now its leaders of surgery struggle through such training. The merit of the system for a few is undeniable, but for the majority its applicability is questionable. Is it not time to initiate a plan that will serve a greater number?

The various insurance schemes for hospitalization have gained great popularity over the past few years, and the trend continues. These programs, in a period of economic prosperity, have been accompanied by a decrease in the number of patients seeking free beds. Many private hospitals dependent on endowment for support have had a reduction in income and an increase in operational expense. These hospitals have had to embrace the insurance plans so far as hospital care is concerned. Ward services have been curtailed, and clinical material for training purposes has been reduced. This is unfortunate because patients properly utilized are benefited when used for teaching purposes. The community hospital properly staffed could, it seems to me, evolve a plan whereby patients would be cared for by the senior and resident staff as they are in the larger teaching centers. Once the system is established in a community and the work is well done, it will have the support of those who use the hospital.

Surgeons of the community hospitals, as well as other members of the medical profession, need no

The graduate training of the medical profession should be considered an important function of the medical schools, and indeed for the past fifty years in the United States they have become increasingly more active in this endeavor. With the requirements so clearly set forth by the various boards, it appears that the medical schools should interest themselves in the graduate training not only in their own hospitals but also in the hospitals within their community or sphere of influence. In some sections of the country, such as Boston and New York, there are several medical schools within a small geographical area. Would it not be a progressive step to enlist the aid of a medical school for a certain number of hospitals or for hospitals within a certain area? When I say aid, I do not mean that they would assume any control over the institution but rather that they would co-operate with the hospitals in the training of young doctors. These hospitals would request the medical school to review their facilities, to advise them on the problems presented by the training.

The medical school would offer the hospitals facilities for training or instruction in the basic sciences as required by the boards, staff members to participate in medical meetings held in the non-medical-school hospitals, a supply of partially trained young men and a stimulus for keeping abreast of current advances. The hospitals would provide the medical-school centers with additional opportunities for the men they had partially trained.

If full use were made of community hospitals with capacities of 150 beds or more whose annual admissions total 5000 to 6000 and over, there would be no lack of positions for training surgeons. A hospital of this capacity and larger that has been built, equipped and staffed to meet the basic requirements of the American College of Surgeons should lend itself to this purpose. I inquired directly of Dr. George H. Miller, director of educational activities of the American College of Surgeons, why these hospitals have not participated more in surgical training. His reply was as follows:

The expression "community hospital" is used with reference to such a wide variety of hospitals that it is a little difficult to discuss it accurately with reference to graduate training. However, I might say that as we are accustomed to think of community hospitals, one of the major obstacles to their participation in graduate training, even in the case of those which are large enough to offer considerable clinical material, is their apparent inability to develop properly organized departments which will place responsibility for the quality of the work done within the department on a recognized department head or chief. They tend to set up a paper organization in which the department headship rotates more or less by courtesy annually, and the members of the staff do not think of the head of the department as having any real responsibility, and sometimes would actually resent any suggestion that the chief was responsible for the quality of any work other than his own. This, of course, does not make a situation in which we can approve the placing of a good resident for training. Many of them also lack in the staff men who have kept up with the recent scientific developments in surgery sufficiently to let them hold a departmental conference and discuss usefully the basic science

interpretation of the clinical problems with which they are dealing.

We are very much interested in encouraging the bringing of such hospitals as far as possible into the sphere of influence of the medical schools through affiliation or collaboration. However, the local problems, except for a few choice endowed community hospitals or strong suburban hospitals near a metropolitan area, prevent the inclusion of many hospitals, which, on the basis of their bed capacity and clinical material, would seem to offer opportunity for graduate training experience.

For hospitals that are large enough and have the facilities to participate in graduate training a general plan is needed. I should favor the division of the clinical work into the four sections of medicine, obstetrics, pediatrics and surgery, each headed by a clinical head on a part-time basis. The hospital of this type requires a full-time pathologist and radiologist. The surgical service is but a part of the hospital, although an important one. The chief, or clinical director, should be well trained, progressive and interested in teaching. He would be the surgical director responsible for the surgery done in the hospital. He and his senior staff should receive pay for the time devoted to teaching the junior staff, which should be composed of residents or fellows. The teaching program should be comprehensive and well planned, with the assistance of the medical-center group. It should include regular ward rounds, staff conferences of the department and general hospital conferences in the form of clinicopathological conferences. All activities in the hospital should be open.

Thus, in these hospitals, men in training would have excellent guidance in diagnosis, preoperative therapy, surgical procedures and postoperative care by the senior staff men. On them would rest the task of correlation of operative data, gross and microscopic pathology and collateral reading or study. Clinical conferences and ward rounds are essential to improvement in the care of patients as well as in the instruction of the trainee. There are many large hospitals in the country that have competent and well trained men who take excellent care of patients but who contribute little or nothing to the instruction of those in training. This is particularly true in municipal, county and private hospitals located in towns and cities without medical schools.

In some cities the medical-school hospitals, long established, have trained the majority of the physicians in the community. The instruction received is reflected in their practice. They are influenced by what goes on in the hospital they were trained in. If they are on the staff of that hospital or a similar one, the influence is greater. This force for advance is lacking in communities far removed from medical schools. This situation, I maintain, can be changed. The medical schools can and should extend their sphere of influence. The materials for this rest in the hospitals that already exist and those that are being established. The medical-center hospital and

Incidence

The exact incidence of dysenteric arthritis is not known, either in the Theater as a whole or in the number of cases in which the diagnosis of bacillary dysentery was made. Arthritis has been encountered relatively often in some epidemics of dysentery and rarely or not at all in others.⁴ For example, a search of the records of the Twelfth General Hospital revealed 20 probable cases of dysenteric arthritis among 173 cases of proved or probable bacillary dysentery — an incidence of 11.6 per cent. At the Seventy-third Station Hospital, on the other hand, the diagnosis of bacillary dysentery was made in 1120 cases during 1943 and 1944, without the recognition of a single case associated with arthritis. Figures in the literature have similarly varied from less than 1 per cent to 5 per cent and over.⁴ Other hospitals in the Theater reported 21 cases of arthritis in association with bacillary dysentery, 10 of which showed conjunctivitis and urethritis in addition. The total number of cases was thus small, and the condition was chiefly confined to the Oran area. One can speculate also that, in a certain number of cases of acute arthritis, the association with dysentery was not recognized, since arthritis is known to occur in mild, easily overlooked cases of bacillary dysentery and even in the carrier state.⁵

Pathogenesis

That dysenteric arthritis is a metastatic infection, with organisms in and around the joints, has not been proved. In only a few recorded cases, in which cultures were taken in the field with opportunity for contamination, have dysentery bacilli been recovered from the synovial fluid.⁴ Since blood cultures have uniformly been negative, an allergic or toxic mechanism has been proposed, and animal experimentation has demonstrated the possibility of either. Finally, as pointed out below in the discussion of Reiter's syndrome, a secondary invader rather than the *Shigella* group may actually be responsible for the arthritis associated with bacillary dysentery.

Diagnosis and Clinical Features

The diagnosis of dysenteric arthritis was established only on a presumptive basis in the Theater, depending on the finding of an acute arthritis and a history of preceding dysentery. In a certain number of cases, stool cultures and agglutination reactions served as confirmatory tests. In the differential diagnosis, other forms of acute infectious arthritis, especially gonococcal, rheumatoid in an acute stage and gouty arthritis, as well as rheumatic fever, were considered.

In the clinical description that follows, since the arthritis was uniformly the disabling factor, no distinction is made between cases with or without urethritis and conjunctivitis. The interval between the first symptoms of dysentery and the development of arthritis varied between a coincidental onset and seven weeks, with an average of sixteen

and a half days. All the cases originated in the warmer months (June through October), the majority occurring in July and August. The arthritis usually arose acutely. Joints were severely inflamed, with effusion, and the course was severe and prolonged. Large joints, with the exception of the metatarsophalangeal, were involved oftener than small, the order of frequency being the knees (75 per cent of the cases), toes (especially the first metatarsophalangeal joint), ankles, shoulders, elbows and hands. In slightly over half the patients, there was bilateral involvement of at least one pair of corresponding joints. In common with other types of infectious arthritis, a few, rather than multiple, joints were affected, but monarticular arthritis was rare. In 9 out of the 20 cases, the arthritis was the only complication and was not accompanied by urethritis or conjunctivitis.

Ten patients also had urethritis which usually followed the onset of the arthritis, but occasionally preceded it. Seven of these had conjunctivitis in addition. The urethritis was usually mild and sometimes not even noted by the patient until he was questioned. In contrast to the arthritis, it cleared readily without specific treatment. No patients were encountered with involvement of other parts of the genitourinary tract, or with balanitis or penile ulceration, as described elsewhere.⁶ Ocular involvement, which occurred in 8 patients, consisted in a mild, bilateral, purulent conjunctivitis, with the exception of a patient with keratitis. All but one of these also had urethritis. The eye lesions cleared up readily, and no patient developed iritis, which was found in frequent association by Beiglböck.⁶

Laboratory findings were helpful only regarding cultures, agglutination tests and determinations of the sedimentation rate. The last was constantly elevated to a high degree during the acute stage of the arthritis, often reaching 100 mm in an hour (Westergren method). Stool cultures were positive in 4 of 17 cases, with organisms identified as *Shigella paradyserteriae* Y in 3 and *S. dysenteriae* in 1. Agglutination reactions to the *Shigella* group were positive in a titer ranging between 1:80 and 1:640 in 8 patients. In a total of 16 patients on whom both tests were done, 11 had either a positive culture or agglutination reaction, or both. Cultures of urethral and conjunctival discharges and of the joint fluid in 1 case were negative. X-ray examination of the affected joints showed only varying degrees of bony atrophy, without destruction, even after several months.

Treatment and Course

Several of the patients had received sulfadiazine or sulfaguanidine, with a favorable effect on the dysentery, but the subsequent development of arthritis was not prevented. Once the arthritis was established, the same drugs were tried unsuccessfully in 8 patients. That the arthritis tended to be

longer consider themselves isolated and in a position where their education cannot be continued. We have a comprehensive current medical literature, which should supplement an adequate medical library in the community hospital. And we have transportation facilities that should enable the profession to attend with ease county, state and even occasional national meetings where new material is presented. The radio and television, which have been used comparatively little for educational purposes of the medical profession, should be employed. Furthermore, by planning, staff members of the community hospital may have a few weeks every year or two during which they can engage in intensive study and observation of new methods as employed in the teaching centers. The United States today holds first place in medical progress, the medical profession, in one way or another, should be made aware of this fact, so that it may make the maximum use of the opportunity that exists. And, in particular, the opportunity should be most profitable for staff members of the community hospitals.

* * *

The development of surgery over the past hundred and sixty years in the United States has brought about the present standards established by the American College of Surgeons and the American Board of Surgery. These appear to be sound. If they can be adhered to, the quality of surgery in the future will be further improved. As indicated above, there are not enough positions in the hospitals that provide the facilities whereby these standards can be efficiently fulfilled. There are an adequate number of medical-school graduates each year who, after a year's internship, seek training in surgery, without success. If hospitals are to

be staffed with board members in surgery, the non-medical-center and community hospitals must equip themselves with the facilities that will enable them to participate in the training of the surgeons who are needed.

In effect, it is proposed that the community hospitals become teaching institutions, that they be the medical centers of the community and that they accomplish this with the advisory assistance and co-operation of a university medical center. Such a plan should materially increase the number of properly trained surgeons that will be needed in the future, what is believed to be of even greater importance is that it will stimulate the physicians associated with these hospitals to keep abreast of advances and create channels through which new information can be easily circulated. Benefits that may accrue from this will be of greatest value to the citizens of the community in which these hospitals function. This appears to be a progressive step in medical care, but it is not a step that can be taken without the whole-hearted co-operation of those who are involved. It requires liberal financing by the community and the support of the medical profession in both the community and the university medical center.

ARTHRITIS IN THE MEDITERRANEAN THEATER OF OPERATIONS*

III Clinical Description of Infectious and Other Types of Arthritis

LIEUTENANT COLONEL CHARLES L. SHORT, MC, AUS

IN ADDITION to the various types of joint disease described in the two previous papers,^{1,2} infectious and miscellaneous forms of arthritis were encountered among United States Army personnel in the Mediterranean Theater.

ARTHRITIS ASSOCIATED WITH BACILLARY DYSENTERY

The arthritis associated with bacillary dysentery, although infrequently diagnosed, seemed of particular interest on account of an unusual symptom-complex that was encountered, especially in the region of Oran, Algeria, in the warmer months of

1943. This syndrome, which consisted in arthritis with conjunctivitis or urethritis, or both, and which has been mentioned in reports in the literature, has already been described by Lieutenant Colonel R. H. Young,³ of the Twelfth General Hospital. A large part of the following material was thus derived from observations made at this hospital, although scattered reports of the type of arthritis under discussion, with or without this symptom-complex, were available from the records of other hospitals. Throughout this section, the term "dysenteric arthritis" is used purely for convenience, with the understanding that, as pointed out below, the *Shigella* infection may merely facilitate involvement of the joints and other structures by a secondary invader.

*The following material represents a condensation and a certain amount of revision of parts of a clinical monograph on arthritis prepared at the direction of the Surgeon, Mediterranean Theater of Operations, United States Army, and submitted to him in final form in June 1945.

activates or provides a portal of entry for the etiologic agent of Reiter's syndrome and that post-dysenteric arthritis is due to a secondary invader rather than to one of the *Shigella* group. This concept is supported by the facts that the organism causing bacillary dysentery has not been found in the joints in cases of arthritis associated with this disease, that the arthritis, unlike dysentery, does not respond to chemotherapy and that the histopathological findings in the case cited above with an acute arthritis following dysentery were typical of a severe case of Reiter's disease.

GNOCOCCAL ARTHRITIS

Incidence

Since the incidence of gonococcal arthritis in the Theater was difficult to determine, only a few representative samples and opinions are presented. A total of only 47 cases were reported by questionnaire from eleven general hospitals. This disease thus accounted for only a small part of the cases of arthritis seen in such installations. Similarly, low figures were estimated for station hospitals, even those handling a large number of patients with gonorrhea, the incidence being regarded as distinctly lower than that seen in the civilian population before the war. The proportion (2.5 per cent) of cases of gonococcal arthritis compared to the total number of patients with gonorrhea in the same general hospitals is surprisingly close to the civilian figure (2 or 3 per cent). This is explainable, of course, by the fact that the general-hospital admissions for gonorrhea were few and confined to cases resistant to therapy. In contrast, estimates as low as 0.2 per cent were received from hospitals primarily handling large numbers of gonorrheal patients.

In World War I a total of 7895 patients with gonococcal arthritis were admitted to United States Army hospitals — about 12 per cent of the arthritic patients, exclusive of those with rheumatic fever.¹² It seems highly likely that a much smaller number of cases were encountered in World War II. This difference was probably due to the specific therapy of gonorrhea with the sulfonamides and penicillin. A number of cases of arthritis occurred, however, after apparent penicillin cure of the urethritis, with an incidence in one station hospital of approximately 0.5 per cent.

Diagnosis

The diagnosis of gonococcal arthritis was made with great care in the Theater, in view of the regulations concerning line of duty and loss of pay that were in force until 1945. Although synovial-fluid cultures were not utilized as often as might seem desirable, the presence of gonorrhea was established bacteriologically, by culture if necessary in nearly every case so diagnosed. It was not generally recognized, however, that a patient might actually have rheumatoid arthritis that had been precipitated by a gonococcal infection of the genitourinary tract.

Such patients undoubtedly made up a number of those considered to have gonococcal arthritis resistant to specific therapy.

Treatment and Results

The treatment of gonococcal arthritis in the Theater was not carried out according to a uniform plan. Sulfonamides, which had been found nearly constantly efficacious in civilian practice, were discarded in favor of penicillin when this agent became available. A trial of penicillin, however, yielded uncertain results, even with a continuous dosage of 200,000 units daily for a week or more. The apparent failure of this method was probably more frequently due to confusion between gonococcal arthritis and rheumatoid arthritis precipitated by gonorrhea than to the existence of gonococcal strains resistant to penicillin in the dosage used. At the same time, conflicting reports on the efficacy of penicillin therapy in gonococcal arthritis appeared in the literature.¹⁴⁻²² In addition, although recent work has shown that an effective concentration in the synovial fluid is obtained with intramuscular penicillin,^{23,24} information to the contrary was available in the Theater.

From the considerations given above, sulfonamide therapy finally became the method of choice, with intra-articular penicillin in addition if possible. The largest series of cases encountered in the Theater was treated by Captain J. D. Phinney, who achieved the remarkably successful outcome of sending 28 out of 30 patients back to full duty. The patients were all given an initial dose of 3 gm. of sulfathiazole, followed by 1.5 gm. every six hours. Those with active gonorrhea or gonococcal conjunctivitis had in addition 200,000 to 400,000 units of penicillin intramuscularly at the rate of 25,000 units every three hours. If possible, an intra-articular injection of 10,000 to 25,000 units of penicillin was given daily for five or six days. One patient with bilateral ankle, knee and shoulder involvement received this treatment in each affected joint for nine days, with full recovery. Although synovial-fluid cultures were not performed, a large majority of patients in this series undoubtedly had gonococcal arthritis. In other reports of the use of a similar plan of treatment, the results were not uniformly favorable, again probably owing to a failure to recognize rheumatoid arthritis precipitated by gonorrhea.

Disposition

The dispositions in 47 cases collected from general hospitals were as follows: to duty, 17 (36 per cent), to limited service, 5 (11 per cent), and for evacuation, 25 (53 per cent). With the exception, then, of the series described above, the available results of treatment seem disappointing at first glance. In many of the cases that were considered failures, however, the patients were probably actually suffering from rheumatoid arthritis.

severe and persistent has been mentioned, but 3 cases were mild and the patients recovered within a few days to three weeks and were returned to duty. Three others were evacuated for other causes, although the arthritis had entirely cleared. The remaining 14 were sent to the Zone of the Interior, with the arthritis slowly but definitely improving in about half. The course of these patients approximated that described in the literature, except that an ankylosing type of dysenteric arthritis,⁴ with resultant permanent disability, was not seen.

Synovial Pathology

No reports on the pathologic histology of dysenteric arthritis have been discovered in the literature. One opportunity, however, presented itself to perform a synovial biopsy on a patient in the acute stage of an arthritis clinically compatible with this condition. The case history and pathologic findings were as follows:

A 31-year-old German prisoner of war was admitted to the Sixth General Hospital on May 29, 1945. He gave a history of an acute, febrile, at times bloody diarrhea from May 5 to May 27. A few days before the diarrhea had ceased, he had developed a painful swelling of the left knee and of the right 2 days later. Examination showed both knees to be moderately inflamed, with effusions—that on the left being more marked than that on the right. The temperature was 101.4°F on admission, falling to normal in 3 days.

Examination of the blood disclosed a hemoglobin of 13.8 gm per 100 cc and a white-cell count of 10,600, with 77 per cent neutrophils. Examination of the urine, a blood Kahn test and two stool cultures were negative. Aspiration of the left knee on June 1 revealed cloudy, yellowish fluid, containing 4425 leukocytes per cubic millimeter, with a differential count of 60 per cent polymorphonuclear cells, 38 per cent lymphocytes and 2 per cent monocytes. An electrocardiogram was normal.

The patient improved steadily, with no medication except large doses of sodium salicylate. On discharge on June 17, examination showed only slight synovial thickening of the left knee and on the right a small effusion and slight limitation in flexion.

About 1 week after the onset of the arthritis in the joint, synovial biopsy of the right knee was performed by Major Otto E. Aufranc. At operation a large amount of pale, yellow fluid with a soft white clot was evacuated. The synovial membrane was slightly pink and edematous, and the small vessels injected. There was no pannus.

Microscopical examination of the biopsied tissue was done by Major Sedgwick Mead, who reported as follows:

The tissue is edematous. Some of the blood vessels in the peritubular fat are ringed with round cells. The subsynovial vessels are dilated, and the cellular infiltrate is more pronounced in this layer. The synovial membrane itself is greatly thickened by the presence of a dense, homogeneous infiltration with large mononuclear cells, lymphocytes and, more rarely, polymorphonuclear cells. Occasional clumps of fibrin are seen, and the articular border is ragged, with nearly complete loss of synovial lining cells. Fibroblasts and new capillaries are growing in the synovial membrane.

Diagnosis: synovitis, acute, severe

Relation to Reiter's Syndrome

In 1916 Reiter,⁷ a German physician, reported the case of a patient with the triad of arthritis, conjunctivitis and urethritis. He believed that the condition was nongonococcal and due to a spirillum that he had isolated from the blood stream. A number of papers have subsequently appeared in the German and Scandinavian literature describing

a similar condition, but in no case has a spirillum been identified. The eponym, Reiter's disease, has persisted, although more descriptive terms have also been applied. Each author makes a distinction between this disease of unknown etiology and similar syndromes associated with gonorrhea and with bacillary dysentery. The first report on this subject in the English language⁸ appeared in 1942 and was followed by one on renal complications in 1944.⁹ All these cases were recognized at the Massachusetts General Hospital, where a series of 10 patients has now been collected. All the patients were men, usually young adults. The clinical manifestations, although often severe and including iritis and pyelonephritis, have thus far eventually cleared, with the exception of mild residual articular changes in certain cases. Recurrences, months to years later, however, have taken place. Extensive attempts to identify a bacterial or virus etiology have been unsuccessful. In February, 1945, Rosenblum¹⁰ reported 10 cases of Reiter's syndrome in personnel of the United States Navy, 5 of which arose in the South Pacific and 5 in the United States. In 2 cases recurrences took place, and one patient with severe involvement of the finger joints showed cartilage destruction on x-ray examination. Another had a widespread, acute skin eruption resembling erythema multiforme. No reference is made in the article to an association with bacillary dysentery. In the same year, 11 cases in the Army were recorded, with diarrhea as the first symptom or accompanying the arthritis in 4.¹¹

During the summer of 1944, of 2 patients with arthritis, conjunctivitis and urethritis admitted to the Sixth General Hospital, neither gave a history or evidence of dysentery or gonorrhea. One exhibited a shallow penile ulcer, which healed spontaneously after repeated negative dark-field examinations. This patient had received 800,000 units of penicillin without benefit. Another patient seen in August, 1943, was of especial interest. While awaiting evacuation for what seemed a typical infectious polyneuritis (Guillain-Barré syndrome), he developed urethritis, conjunctivitis and arthritis in rapid succession, without findings pointing toward dysentery or gonorrhea. In view of the reported incidence of polyneuritis,¹² presumably of toxic origin and secondary to bacillary dysentery, the possibility is raised of a common etiology for all the clinical manifestations of this patient.

A relation between the arthritis, urethritis and conjunctivitis following bacillary dysentery and Reiter's syndrome is immediately suggested from the essentially identical clinical pictures. It seems fair to assume that such an unusual symptom-complex probably arises from a single cause. Although, as pointed out above, Reiter's syndrome may be preceded by or associated with diarrhea, no evidence has yet been presented that an active or latent *Shigella* infection is responsible. A more logical explanation is that the dysentery merely

tism,³⁰ was diagnosed twice at the Three Hundredth General Hospital

SUGGESTIONS FOR IMPROVEMENT IN TREATMENT

Segregation of patients with arthritis in special hospitals or dispensaries is unnecessary in an overseas theater, but more efficient handling of such cases seems possible within the existing medical installations

Provision should be made in the forward areas for rapid examination and disposition of patients with articular symptoms to avoid the sending of large numbers to base hospitals. For officer personnel, an internist with interest in and some special knowledge of joint disease, an orthopedist and a psychiatrist should constitute a team. Laboratory requirements could be held at a minimum but x-ray examination would be necessary, especially in patients with back symptoms. Many of the patients with arthralgia or psychogenic rheumatism could thus be sent back to duty after a relatively short period of examination and treatment, and those with a real arthritis or doubtful cases evacuated to base hospitals

In general and station hospitals, one officer, preferably on the medical service, should be given the arthritic diseases as an assignment. Although he should be experienced and interested in arthritis, it would be his duty to perfect his knowledge of the subject in every way possible. He should see all cases of joint disease in consultation and thus constantly teach himself as well as the other ward officers. Cases of especial interest or difficulty could be transferred to his own wards. He should be responsible for the policies followed in the hospital for diagnosis, treatment and disposition of patients with arthritis and should personally handle such curable conditions as gonococcal arthritis. He should work in close co-operation with orthopedic and neuropsychiatric officers and with the laboratory and x-ray services. In this way, the problem of arthritis in fixed hospitals in an overseas theater could be handled to greater advantage, with a consequent reduction in hospitalization and manpower loss.

SUMMARY

Arthritis associated with bacillary dysentery was rarely diagnosed in the Theater, except in the Oran, Algeria, area during the summer of 1943. In many of these cases, urethritis and conjunctivitis were present, with a clinical picture closely resembling Reiter's syndrome. Evidence is presented that the Shigella infection merely facilitates involvement of the joints and other structures by a secondary invader.

The incidence of gonococcal arthritis was less than that found in prewar civilian practice, probably owing to early, specific treatment of gonorrhea.

Cases were recorded, however, after apparent cure of the urethritis with penicillin. The explanation of the unsatisfactory results of therapy probably lies in the failure to recognize rheumatoid arthritis precipitated by a gonococcal infection.

Suggestions are made for the more efficient handling of joint disease in an overseas theater.

MENINGOCOCCAL ARTHRITIS

Meningococcal arthritis was generally associated with meningococcal meningitis. Only 9 cases were encountered, the incidence of this complication being 5.3 per cent in 170 patients with meningitis in general hospitals. This figure is in general agreement with civilian and military experience in the United States.²⁵⁻²⁷ No essential difference was noted in the clinical features of the disease in these cases as compared with those observed in the United States or reported in the literature. Whereas the arthritis was occasionally found on admission, it was usually not recognized until four or five days had elapsed. The reasons for this apparent latent period are obscure. Early involvement of the joints probably takes place, but frank signs and symptoms of arthritis develop later or are not immediately noticed in an unresponsive patient in whom attention is directed toward the much more serious localization of the infection in the meninges.

As in the cases observed in the United States,^{26, 28} prior administration of the sulfonamides or penicillin neither prevented nor lessened the incidence of arthritis. Although mild, transitory involvement of multiple joints might come first, the process eventually settled in one or a few large joints, chiefly the knee. Inflammatory signs were variable, and some joints were acutely swollen and painful at the onset. Since serum was not used in the Theater, no question of serum sickness arose, and only a few synovial-fluid cultures were performed, with negative results. The course of the arthritis was not strikingly influenced by chemotherapy or penicillin, although intra-articular injections of the latter were not tried. Important points that were sometimes neglected in the management of knee cases consisted in the avoidance of fixation, the postponement of weight bearing until the inflammation cleared and the early use of quadriceps exercises. The severity of the arthritis varied, but most of the patients required four to six weeks' convalescence before function was fully restored. All were returned to full duty, with the exception of 1 patient with mild residual changes in the knees, who was sent to limited service.

Meningococcemia without meningitis was reported in 26 cases, with one evacuation hospital furnishing 5 cases.²⁹ This condition was often accompanied by pain in the region of the joints—sometimes caused by embolic skin lesions—and occasionally by a frank arthritis. The cases were often confused at first with rheumatic fever or erythema nodosum, the diagnosis usually being made finally on the basis of the typical picture,²⁹ although a few positive blood cultures were obtained. Cure and rapid return to full duty were accomplished in every case with the aid of chemotherapy, usually sulfadiazine.

GOUTY ARTHRITIS

This form of arthritis was carefully looked for in the hospitals in the theater, but only 15 cases

were reported. In World War I, a total of 82 such cases were admitted to Army hospitals.¹² In some cases in the Mediterranean Theater, the diagnosis was made on equivocal blood uric acid findings, without a characteristic clinical picture. A lack of colchicine prevented treatment of acute attacks and possibly, in certain cases, return to duty. Ten patients were considered unable to perform any sort of duty in the Theater and were evacuated. The remainder, chiefly officers with sedentary assignments, were able to resume their duties.

MISCELLANEOUS TYPES

Only 3 cases of tuberculous arthritis were reported from general hospitals in the Theater. The incidence in World War I was similarly low, a total of 188 patients being admitted to Army hospitals.¹³ In 2 cases, in which a knee and a hip were respectively involved, the diagnosis was obvious, but in another, a second biopsy of the ankle joint was required for an unquestioned diagnosis. All the patients were evacuated to the Zone of the Interior.

A diagnosis of undulant fever was made in 34 patients in general hospitals, a number of whom presented articular symptoms. None of these cases were confused with any type of arthritis except for one patient with multiple joint involvement, another with a suppurative knee requiring drainage and a third with osteitis of the spine.

Scarlet fever was rarely accompanied or followed by arthritis, but a few patients manifested a recrudescence of rheumatic fever, and two others a transitory arthritis.

A patient with a staphylococcal infection of the wrist of unknown origin, which was surgically drained, was the only one reported with a septic joint not associated with trauma.

Patients with certain infectious diseases presented themselves with skeletal aches and pains at the onset. Most conspicuous among such symptoms were the arthralgia occasionally noted in acute hepatitis, the severe pain and stiffness in the cervical region of sandfly fever and the exquisite tenderness resulting from the muscular localization in Weil's disease.

No case was observed in which arthritis could be attributed to amebic dysentery, malaria, granuloma inguinale or coccidioidomycosis. There were 3 cases of arthritis associated with lymphogranuloma venereum, but details were not available regarding the probable relation of the arthritis to this venereal disease. Acute disseminated lupus erythematosus, a rare disease and one that is much more frequent in women than in men, was diagnosed at least twice, but there were no articular symptoms that might have caused confusion. One patient with a joint condition resembling rheumatoid arthritis was suspected of but not proved to have periarteritis nodosa. The most recently described syndrome among the arthritides, palindromic rheuma-

urinary analyses, physical examinations, x-ray studies and blood Wassermann tests had been made. Of this group he studied in detail three sections — those with a family history of diabetes, those with a hereditary history of diabetes and those who had shown sugar in the urine. He writes, "What a wonderful work in preventive medicine it would be if

65 and over	14.58	21.47	7	1	120.0

we could identify all the persons having diabetes and potential cases of diabetes in the United States."

For diagnostic purposes Gate employed in blood sugar determinations the Myers-Bailey modification of the Lewis-Benedict method. Venous blood samples were used. The following is an account of Gate's findings.

The starvation blood sugar should be 0.14 per cent or more and the post-prandial should be 0.22 per cent. The blood sugar should not fall so low as the starvation sugar at the end of two hours, and there must be accompanying glycosuria.

We have classified potential cases of diabetes as follows: Those whose starvation blood sugars were under 140 milligrams, whose peak did not rise to 220 milligrams, whose two-hour blood sugar did not fall to 140 milligrams, but may have nearly approached it, and who have accompanying glycosuria. The higher limits of blood sugar have been used because the blood sugars usually run higher with this method of determination.

We have done glucose tolerance tests on 109 individuals. Seventy of these individuals had given a history of having some relative who had diabetes, 43 had shown sugar in the urine, and four had shown sugar in the urine and also had given a positive history.

Realizing that the glucose tolerance test may be inaccurate if the individual has been restricting his diet, no tests were done on persons who had been restricting their diet in any way. The glucose tolerance test, which we used, was as follows:

Each individual reported in the morning without breakfast and having had no food for approximately sixteen hours. A sample of venous blood was obtained and a specimen of urine, 100 grams of glucose in solution was given orally and samples of blood and urine were tested at one-half-hour, one-hour, two-hour, and three-hour intervals.

In Table 1 the incidence of diabetes found by Dr Gate is compared with that obtained by a house-to-house canvass conducted by the National Institute of Health.⁸ (A personal communication from Dr Gate disclosed that 159 of his 1800 subjects were females.) Instead of an average incidence of 1.200, as would be expected from the National Health Survey, Gate found a total of 20 diabetic patients, or 1.90.

Glucose-tolerance tests were performed in the 8 cases with a family history of diabetes, in 63 with a

hereditary history and in the 46 in which examination showed sugar in the urine. Eight patients were known to have diabetes, and in 8 with family histories of the disease the tests revealed no diabetes, 9 of the 63 with a hereditary history showed diabetes, and 11 of the 46 with sugar in the urine were so classified, but 8 of these had previously been known to have the disease. One case with a family history, 8 with a hereditary history and 10 with sugar in the urine, but without history, were classified as potential cases. Gate concluded that the incidence in this particular group was about twice what might be expected as compared with published estimates.

Gate observed a great deal of interest among the persons interviewed while this work was in progress. Many of those who had a familial history of diabetes or near relatives with diabetes had apparently been wondering whether or not they would develop the disease. Some had been assured by their physicians that they need not worry, others were extremely interested in having the glucose-tolerance test performed.

No difference in the incidence of diabetes was observed between subjects working in the office and laboratory and those who did varying types of operation and labor in the plant itself. The study concludes as follows:

Further investigation along similar lines in other groups even without glucose tolerance tests, but with random blood sugars, would yield very valuable information, and unquestionably would uncover many hitherto unrecognized diabetics.

The greatest benefit resulting from this investigation is not that we may have shown that the actual incidence of diabetes is higher than has been estimated previously. The real value is that we have found a number of individuals who did not know they had the disease and who now will be able to prolong their lives. Then, too, a goodly percentage of those who are potential cases may be able to avoid the disease because they have been forewarned of the danger.

DIABETES IN BERGEN

A notable article of the year is that by Hanssen,⁹ who was senior assistant in the medical department of the City Hospital of Bergen, Norway, between 1940 and 1943, having previously worked in Denmark under Hagedorn. His monograph includes a study of the morbidity, mortality, causes of death and complications of diabetes mellitus in Bergen from 1925 to 1941. The investigation was so thorough that no similar research of just this type is apt to be attempted soon, and in fact, I think that all of us should concentrate more and more on the study and care of present-day cases. The monograph not only covers data relating to the diabetic patients in Bergen but also includes the literature in both Europe and America, and in it will be found many valuable citations sometimes overlooked in this country.

Bergen's population was about 100,000, of whom 45 per cent were males. Since there is little migration of the inhabitants in Norway it was easy to trace the diabetic patients. There were few Jews

MEDICAL PROGRESS

DIABETES MELLITUS

ELLIOTT P JOSLIN, M D *

BOSTON

THE most notable achievement in diabetes mellitus during 1946 I consider to be the demonstration by Lukens and Dohan,¹ of the Cox Metabolic Unit, University of Philadelphia, of a fourth method by which the disease can be caused experimentally in animals. They accomplished this by the production of hyperglycemia in a cat for a period of two weeks. It will be remembered that Haist, Campbell and Best² showed that by the simultaneous administration of insulin, diabetes can be prevented in a dog receiving injections of anterior pituitary extract and that Lukens and Dohan^{3,4} prevented and "cured" the diabetes in a cat following injections of pituitary extract by overcoming the subsequent hyperglycemia and maintaining the blood sugar at a normal level by means of insulin, diet or phlorhizin. It is known that in animals in which a subtotal pancreatectomy has been performed, just as after injections of anterior pituitary extract, a period of hyperglycemia precedes hydropic degeneration. On the theory that if the prevention or lowering of hyperglycemia is useful its causation should be harmful, Lukens and Dohan, by intraperitoneal administration of glucose, induced hyperglycemia in cats, and after two weeks in an animal in which this condition prevailed they found diabetes accompanied by changes in the islands of Langerhans, including hydropic degeneration. Technically this is a notable achievement, as attested to me by Dr F M Allen, because of the difficulties generally encountered with experiments on this animal. Lukens and Dohan write as follows:

In summary, hydropic degeneration of the islands of Langerhans and permanent severe diabetes mellitus have followed the prolonged injection of intraperitoneal glucose-saline solution in normal as well as in partially depancreatized cats. Positive results were associated with prolonged hyperglycemia. These findings add further evidence in support of the hypothesis that a sustained elevation of blood glucose may, under certain conditions, lead to the production of damage to the islands of Langerhans in this species.

The importance of hyperglycemia in the etiology and treatment of diabetes is emphasized by Ricketts,⁵ of the University of Chicago, who marshals the evidence on this topic in so masterful a way that his study should be "must" reading for every medical student as an ideal presentation of the subject and for each doctor interested in diabetes because of its assembly of facts regarding the disease.

*Clinical professor of medicine emeritus, Harvard Medical School; medical director, George F Baker Clinic, New England Deaconess Hospital.

Naturally, to those who believe heart and soul in the aggressive treatment of diabetes advocated by Naunyn, these papers are welcome. They fortify the thesis that control of the disease pays and confirm the opinions of Joslin et al,⁶ as well as helping to explain why the patients who closely follow this dictum are the ones freest of complications.

An example of such patients is afforded by a man (Case 2419) who developed the severe diabetes of childhood at the age of fourteen and a half years in 1920. For about ten years he had as skilled a diabetic nurse as I know. He meticulously followed the orthodox treatment of a low-carbohydrate, low-calorie diet, in addition to insulin and exercise, and the nurse even accompanied him when he piloted his own aeroplane on week-end trips. At twenty-six years of age he married a nondiabetic girl from a nondiabetic family, who in preparation spent nearly six months learning the principles of diabetes control in the house of the patient's mother. They now have three healthy children. A few months ago in a train wreck he sustained ten broken ribs, a punctured lung, a fourfold fracture of the scapula and a compound fracture of the wrist, and yet at the end of four weeks, on discharge from the hospital, he was told by his surgeon that his recovery had been as rapid as that of a nondiabetic person. The diet included 175-200 gm of carbohydrate, 60-75 gm of protein, 90-100 gm of fat, and 18 units of crystalline and 70 units of protamine zinc insulin daily.

Another patient (Case 2568) developed diabetes at the age of seven years and nine months. She followed a strict regime of fasting and was one of the first to take insulin in this country, under the supervision of Dr F M Allen. After twenty-five years of diabetes a third healthy baby was delivered—a triumph for the patient's courage and the combined skill of Drs Priscilla White, Raymond Titus and Warren Sisson.

STATISTICS

In 1942 Gate⁷ published a careful study, unfortunately overlooked, of a group of 1800 patients with examinations of the urine and blood with the purpose of identifying those who had diabetes or might develop it and of prolonging the lives of the former and possibly postponing or preventing the full development of the disease in the latter. For this survey Dr Gate utilized the employees of a large manufacturing concern on whom yearly

aminated. No relation was detected between the duration of the diabetes and the frequency of calcification or with high serum cholesterol figures (not less than 220 mg per 100 cc.) No great difference in the incidence of arteriosclerosis as shown by the roentgenogram was found between male diabetic patients over forty years of age (56 per cent) and nondiabetic patients with diseases of the heart, kidneys and blood vessels (67 per cent) or from another group without such diseases (50 per cent). For women the incidence was definitely higher in the first two

TABLE 3 Lesions Discovered at Autopsy in 429 Cases of Diabetes

LESION	CAUSE OF DEATH NO OF CASES	COMPLICATION NO OF CASES
Coronary sclerosis	6	177
Coronary occlusion with infarction	87	26
Myocardial failure	18	68

groups (37 and 33 per cent) than among those in the third and younger group (13 per cent). Therefore, the high frequency of arteriosclerosis on roentgenologic examination of diabetic patients demonstrated by Joslin and his associates is not confirmed.

Some of the patients with demonstrable arteriosclerosis showed signs of a defective arterial blood supply to the lower limbs, but no connection between these phenomena was demonstrable.* The reduction of the arterial blood supply to the lower limbs was first and foremost due to thickening of the intima that is not demonstrable on ordinary x-ray examination. This is also why the demonstration of such arteriosclerosis is of no special prognostic significance in any given case, diabetic or otherwise.

Among Hanssen's 292 diabetic patients whose deaths were due to known causes, the deaths from heart disease were attributed to arteriosclerosis and hypertonia in 15 per cent of the male and 16 per cent of the female patients. Among the 108 diabetic patients examined post mortem were 9 who died of heart disease, which in 5 cases consisted of infarct of the heart and in 4 of heart failure. In contrast, 44.5 per cent of cases in the Joslin series of 651 deaths, outside and in the hospital, from January 1, 1944, to May 15, 1946, were cardiac deaths,¹² but it should be pointed out that this series is at a distinctly later period. Among 429 deaths at autopsy at the George F. Baker Clinic, 111, or 26 per cent, were due to heart disease, the percentage having risen from 22 in 1940.¹⁶ Table 3 presents the types of lesion discovered at autopsy in the most recent Warren-Joslin group of 429 cases. Again, the longer duration of the diabetes, especially in patients dying

*The high percentage of arteriosclerosis in the legs of young diabetic patients in the Joslin group is believed to be due, first, to the low level of nutrition of these young people, who were treated just before or just after the discovery and use of insulin in 1922, secondly, to the low-carbohydrate and relatively high-fat diet in the period mentioned, and thirdly, and above all, to the exceptionally long duration of the diabetes in these youthful patients of whom we have had a relatively large number.

under fifty years of age, and the increasing age of these relatively young patients at death are considered factors that distinguish this group from those in the Norwegian study. Hanssen cites Wilder as emphasizing the great frequency of severe coronary sclerosis in female diabetic patients and refers to the paper of Root et al.¹⁷ in which the incidence of death from coronary occlusion among diabetic male patients was twice to four times as high as that among nondiabetic men of the same age group and four to ten times as high among diabetic as compared with nondiabetic women.

Cerebrovascular accidents, in contradistinction to cardiac disease, were more frequent (18.8 per cent) in the Bergen group than in either the 1946 series (9.4 per cent) or the 1944-1946 series (11.4 per cent) of Joslin. All data agree that the incidence of such accidents is much higher in female patients.

Although no cases of acute or chronic nephritis were observed by Hanssen, albuminuria was present in 5 per cent of the men and 7 per cent of the women over fifty years of age. The difference between these data, which represent a former epoch, and those in our experience with children with diabetes of long duration is expressed by Dr. Priscilla White,¹⁸ who states that between 1940 and 1946 nephritis had become the chief cause of death in patients with the onset of diabetes in childhood. In 84 cases of childhood diabetes of more than ten years' duration, 31 patients died of nephritis. Premature development of arteriosclerosis is already yielding to better dietary and insulin treatment. Under forty years of age, severe grades of intercapillary glomerulosclerosis were found in 13 of 40 cases at post-mortem examination.¹⁹

Gangrene was responsible for 11 of 125 deaths in the Bergen City Hospital. Amputations were far more numerous in the Oslo City Hospital than in the Riks Hospital in Oslo. In the Joslin series, the incidence of deaths from gangrene in 651 cases from 1944 to 1946 was 2.9 per cent, — a decrease from 4.4 per cent in the earlier series — but in the series of cases at autopsy the incidence was 12 per cent, as compared with 13 per cent in the earlier group. A percentage increase in the deaths from gangrene would not have been surprising, because of the growing number and relatively higher percentage of such cases in patients admitted to the George F. Baker Clinic, despite the lowering of surgical mortality. Hanssen calls attention to the frequency of gangrene in female patients.

For comparison two analyses (Tables 4 and 5) are given that demonstrate, respectively, the effect of the duration of diabetes on the mortality in cases in which the patients died of arteriosclerosis and coma and the changing sites of arteriosclerosis at successive periods. These tables are based on Tables 58 and 60 in the study of Joslin et al.,⁶ which had not appeared when Hanssen's article was written.

In general, the diet was low in calories and carbohydrate but relatively high in fats. Insulin was used in moderate amounts, being available for all and protamine zinc insulin having been employed since 1936. There were 392 deaths from diabetes between 1925 and 1941 and 402 known living diabetic patients in October, 1941, making a total of 794 cases. These figures were obtained from death certificates, cases treated in the City Hospital, patients listed for supplementary food rations and the complete replies received from questionnaires sent to physicians.

Particular attention was paid to arteriosclerosis, examination of the heart, the vessels in the right leg and the eyes, as well as electrocardiograms, being utilized.

The ratio of the 402 diabetic patients to the general population in Bergen in 1941 was 3.2 per 1000 males and 4.3 per 1000 females, the average being 3.8 per 1000, of whom 43 per cent received insulin. For a comparison, in Oslo the incidence — on the basis of patients receiving supplementary rations on July 1, 1943 — was 4.3 per 1000, of whom 54 per cent were receiving insulin. The author cites Falta as giving the incidence of diabetic patients in Vienna in 1940 as 5 per 1000 population.

The age at onset of the disease is placed at a decade later in life (sixty to sixty-four years) in Bergen than in the United States. Of the total of 794 cases there were only 29 with onset under the age of fifteen years, or about half the percentage in the Joslin series.

Just as Lombard and Joslin¹⁰ noted the unreliability of computing morbidity rates from mortality figures, Lundberg, cited by Hanssen, wrote in 1938, "It is probable the time will soon come when it will be quite impossible to employ the mortality figures for estimating the frequency of diabetes in the population." As a matter of fact, in Bergen from 1925 to 1941, only 58 per cent of the male and 68 per cent of the female diabetic patients were registered as having died of the disease. These figures are similar to those of 62.9 and 64.3 per cent for Massachusetts in 1936 and 1946 found by Lombard and Joslin and that of 69.4 per cent observed by Palmer¹¹ in Seattle.

Of the 392 deaths in Hanssen's study, 125 occurred in the City Hospital, and of these, 108 cases were autopsied. Table 2 presents the causes of death in the Joslin¹² group of cases as compared with those in the Hanssen monograph.

The treatment of diabetic coma in Hanssen's group was similar to that employed in the George F. Baker Clinic, glucose and alkalies being omitted. The predominant cause of the high case mortality was the delay of treatment.

Under fifty years of age hypertonia was exceptional. Above that age both systolic and diastolic hypertonias were frequent, 43 per cent of the male and 68 per cent of the female patients with blood

pressures of over 160 systolic, 100 diastolic, as compared with 25 per cent of the normal men and 36 per cent of the normal women of the same age group. Blood pressures over 201 systolic, 121 diastolic, were observed in 10 per cent of male and 23 per cent of female patients. Hanssen notes that elderly people tend to have a high systolic but not a high diastolic

TABLE 2 Causes of Death among Diabetic Patients in the Series of Hanssen⁹ and Joslin¹²

CAUSE OF DEATH*	HANSEN SERIES		JOSLIN SERIES	
	(1922-1936)	(1925-1941)	(1937-1943)	(1944-1946)
	PERCENTAGE	PERCENTAGE	PERCENTAGE	PERCENTAGE
Diabetic coma	8.4	8.2	3.4	3.1
Arteriosclerosis	53.8	48.0	64.0	66.6
Infection	13.6	22.0	11.5	7.8
Tuberculosis	4.2	4.1	2.6	2.5
Cancer	8.8	8.6	8.8	8.9

*There were 392 deaths in Hanssen's series. In the Joslin series the total deaths were, respectively, 2583 and 651 in the periods 1937-1943 and 1941-1946.

pressure. He observed that diabetic retinitis was particularly frequent in diabetic women.

Arteriosclerosis was observed more frequently at autopsy in the Bergen series than in that of Warren¹³ presumably because 84.5 per cent of patients in the former were over fifty years of age in contrast to 67.5 per cent of those in the latter. On the other hand, coronary occlusion occurred in only 6 per cent of cases in the Bergen series, in contrast to 20 per cent in that of Warren. The heart weights were greater in the Bergen series, but the patients were older and comparative body weights were unknown.

Comparisons of the incidence of arteriosclerosis in different communities are open to serious criticism, and Hanssen cites Björnsson's¹⁴ observations regarding this problem in Iceland, Copenhagen and Vienna. Local factors, sex, occupation, environment (town or country) and peculiar or different hospital conditions may have been of great significance. General impressions, unsupported by an actual analysis of available material, are not conclusive, clinical investigations are not sufficiently accurate, and even pathological and anatomical data really depend on the subjectivity of the pathologist.

Roentgenologic examinations of the arteries of the leg were carried out on 451 diabetic patients in a search for calcification. Calcification was rare under the age of forty years but increased with the patient's age, being found above forty years of age in 56 per cent of the men and in only 37 per cent of the women in the same age group despite the greater frequency of systolic and diastolic hypertonia in the female patients. Extensive calcification, however, was more frequent among female diabetic patients than among the nondiabetic women ex-

*Studies of the pelvic arteries were not made. During the last five years Dr. Priscilla White¹⁵ has found that when the pelvic arteries are visualized in a pregnant woman the prognosis for a living child is definitely less favorable than otherwise. Thus many of these patients abort and only 20 per cent have had a living child regardless of whether or not they are treated with hormones. Dr. White considers a ray examination of the pelvic arteries to be of the greatest importance.

practice is essential to furnish the rapidly growing number of diabetic patients the treatment they need

To live successfully with diabetes one must know the rules, and to teach these to patients is the function of the physician. In the first place, this demands more time than the doctor has at his disposal, and in the second place, it would cost the patient too much. Therefore, the doctor must get someone to do the elementary teaching for him — his wife, his child, his nurse, his secretary, his technician or another patient whom he has helped. The doctor must utilize the services of someone else, but that is not the whole of the story. At stated intervals he should assemble his patients, young and old and those with diabetes of long and short duration, and conduct a class for an hour or so. This will obviously cost the patient less than the \$8.00 a day, in addition to laboratory fees, in a ward bed in a hospital, in addition, the physician will receive his return, because he will constantly be building up a group of patients who come back out of necessity for regulation or follow-up over a period more than three times as long as formerly.

The Clinitest apparatus,* although by no means perfect, simplifies the treatment of the patient enormously, and I believe that before long a simplified blood sugar test will be available. A better use of neighborhood laboratories should be made. The diabetic patients themselves should be encouraged by small contributions to bring the laboratories up to date as a protection in times of emergency.

THE CHANGING TYPE OF HOSPITAL PATIENTS

The type of diabetic patients treated in hospital wards has greatly altered, and our experience is doubtless only an epitome of that of others. In 1941 the average duration of the diabetes of the patients in our group treated at the New England Deaconess Hospital was seven years and one month. Recently, a survey revealed that patients at the same hospital had already had the disease on the average well up toward thirteen years or almost within a year of the average duration of life in all the fatal cases in the Best Era. Only 1 in 10 could attend the diabetic classes held in the adjoining George F. Baker Building, and only a few weeks later a similar survey of 34 patients showed that only 1 in 7 could attend class. For every three years since the discovery of insulin the duration of life of diabetic patients, on the basis of our fatal cases, has risen one year, it is evident that the backlog of old and crippled diabetic patients will increase and thus fill hospital beds. And the tragedy is that these patients, who have fought the disease for years and whom we respect and are glad to help, are seldom likely again to be self-supporting. Yet each of them by a prolonged stay will bar from entrance a multitude of

young patients fully capable of being taught in a brief time to be efficient for years. This is why the family doctor must enter into the picture far more than ever before. It is he who can protect these thousands of diabetic patients. Contrary to many, I believe that, because of things like this, the future will, or at least can, bring the family doctor into his rightful and important place in medicine.

PREGNANCY IN DIABETES

The obstetric series of White, Titus and Sisson continues to expand. It is to be hoped that similar reports of a similar class of diabetic patients — namely, those of considerable severity and long duration — will appear for comparison. Summaries for 271 cases are presented by Joslin et al.,⁶ and the data in 23 cases of diabetes of twenty or more years' duration will be published in the March, 1947, issue of the *Medical Clinics of North America*.

The principles underlying their methods consist primarily in meticulous care of the patient with the realization that renal glycosuria is a major factor in pregnancy and that one must provide for sufficient calories to be utilized by the mother and the fetus, at the same time, with the multiple doses of insulin often required, the patient must be protected against hyperglycemia.

Toxemia of pregnancy, they believe, can be anticipated and often controlled by hormonal changes, its appearance in the latter months of pregnancy is always accompanied by albuminuria, a rising blood pressure and a gain in weight. Irrespective of these possibilities, delivery is usually favored in the thirty-seventh or thirty-eighth week by cesarean section. The healthy-appearing baby, however, should receive the attention given to a premature infant. Careful drainage, suction and oxygen and an incubator are indicated. The infant should receive no food or drink for one to three days. Obviously, the management of pregnancy in a mature multipara with slight, or even temporary, glycosuria, does not require such drastic measures.

In the presence of a rising serum chorionic gonadotropin level, diethylstilbestrol is injected daily and in increasing doses, and conversely when the urinary pregnanediol is falling, Proluton is administered daily. Even though the pregnancy is uncomplicated I gather that Dr. Titus prefers to deliver the hormonally treated patient rather than one who has not received such medication.

The latest results are 330 deliveries since January 1, 1936, with a single maternal death from hepatitis, as shown by autopsy, six weeks after delivery. The survival of infants prior to 1936 was approximately 50 per cent. In the present series, the survival rate in 61 cases of complicated pregnancy in which the mothers were not treated was 46 per cent, that in 198 complicated cases treated with hormones was 90 per cent and that in 71 uncomplicated cases, in

*Manufactured by Ames Company Incorporated, Elkhart, Indiana.

Hanssen noted the rapid disappearance of large livers in young diabetic patients following the more adequate treatment and control of the diabetes that the introduction of protamine zinc insulin made possible, an observation also made by White et al.²⁰ Acute hepatitis and hemochromatosis were not encountered. Gallstones were no more frequent among male diabetic patients than among the controls, but

Discrepancies between the official data of mortality and the true facts of diabetic patients dying with the disease but not of it are readily explained. Before 1914 approximately two thirds (63.8 per cent) of all diabetic patients here and abroad died of diabetic coma, an easily recognized and recorded diabetic death. Today, only 3.1 per cent of diabetic patients in our group die of coma. Approximately

TABLE 4 Influence of Duration of Diabetes on Mortality in Patients Dying of Arteriosclerosis and Diabetic Coma⁶

PERIOD	AVERAGE DURATION OF DIABETES*	TOTAL NO OF DEATHS	DEATHS FROM COMA	DEATHS FROM ARTERIOSCLEROSIS	AVERAGE AGE AT DEATH

*Based on cases of known duration

they were encountered oftener in female diabetic patients. There were 2 cases of cancer of the pancreas, but none of acute necrosis of the pancreas or of pancreatic calculi. The morbidity and mortality from tuberculosis were not of any great importance, — 4.1 per cent, — in contrast to the high incidence

9 per cent die of cancer, instead of 1.5 per cent as heretofore, diabetes thus losing precedence in statistical enumeration, 67.4 per cent died of cardiorenal vascular complications in the period since 1944, as compared with 17.5 per cent in that from 1898-1914. These and other facts regarding the causes of death

*Tabulation by the Statistical Bureau of the Metropolitan Life Insurance Company

of the disease among diabetic patients in various European centers, notably Paris and Vienna.

What is really needed for a better understanding of both the incidence and the clinical features of diabetes is a survey of isolated localities all over the world, such as that now in progress in Oxford, Massachusetts, a town of 5000 inhabitants. Such surveys will give a true idea of the morbidity of the disease. For a knowledge of the mortality one must depend more and more on private statistics from private clinics and groups of physicians particularly interested in the disease who follow up all their cases, here again discrimination in the evaluation is necessary on account of varying local conditions

of 8384 diabetic patients in our series, as well as data from various international compilations, have recently been summarized.¹²

MEDICAL TREATMENT

Hospital costs for diabetic patients are rising, but I am sure that all physicians appreciate the fact that the cost of medical care should be and, indeed, is decreasing. The reason is plain. Hitherto the diagnosis of diabetes was usually made among the well-to-do, but a lower economic stratum of society is receiving better medical care and these patients simply do not have the money to pay for the services formerly rendered. A reorganization of medical

CASE 33131

PRESENTATION OF CASE

A fifty-four-year-old Irish retired elevated-rail-road employee was admitted because of shortness of breath.

For the previous ten to fifteen years he had had attacks of asthma occurring at night during which he was short of breath and coughed. He was usually somewhat relieved when he brought up phlegm, which was white and thick, and he was able to breathe much better sitting up. When he had such attacks he usually spent the rest of the night in a chair and was over the attack by morning. A physician gave him "pills" for the asthma. The attacks had recently increased in frequency. For the preceding two years the patient had noted shortness of breath on exertion, particularly during the day, and the ankles had begun to swell. He was given digitalis, which he had taken irregularly ever since. The salt intake had been reduced. An electrocardiogram a year before admission had revealed auricular fibrillation (Fig 1). On fluoroscopy the heart was moderately enlarged, and there was a prominent pulmonary artery and questionable enlargement of the left auricle. The heart sounds were distant, and no murmurs were heard. During the year the symptoms had become progressively worse, with occasional remissions, and the patient was forced to quit work. For three months before admission he had been unable to negotiate three flights of stairs. The legs swelled progressively up to the thighs, and the abdomen had become swollen. He had taken some digitalis for a few days before admission. His physician had given him mercurial diuretics.

The patient remembered having had "rheumatic fever" at the age of seventeen, when he had been kept in bed with swollen joints and had felt quite sick for about six weeks, but he knew of no heart murmur and had subsequently had no swollen joints, nosebleeds, chest or abdominal pain. He had never had high blood pressure. Up to two years before admission he had drunk one or two glasses of beer and half a pint of whiskey a day, but this had been almost entirely omitted since then.

Physical examination revealed a florid, extremely cyanotic, obese, well developed man with signs of weight loss in the face and upper extremities. He was partially sitting up in bed and breathing with moderate difficulty and with audible coarse wheezing. There was questionable icterus in the scleras. The fundi showed mild arteriosclerotic changes. There was a moderate rhinophyma. The neck

FIGURE 1

veins were full but not pulsating. The heart was enlarged to the left, reaching the anterior axillary line, with a forceful apical beat in the fifth inter-space. The rhythm was irregular and alternated between bigeminy and trigeminy with an apical

which the mothers were not treated with hormones, was 97 per cent

SURGERY

Reference is made to a recent article by McKittrick²¹ in which advances in the surgical treatment of complications of diabetes have been set forth. Suffice it to say that, whereas in the period 1923-1941 the mortality for amputations through or above the mid-lower leg was 14.1 per cent in 609 cases, in 1942-1945 it had dropped to 4.7 per cent in 212 cases, and that for major and minor amputations it had similarly dropped from 9.7 per cent in 1036 cases in 1923-1941 to 2.6 per cent in 229 cases in 1944 and 1945. This is undoubtedly due in large measure to the use of the sulfonamides and penicillin. But technically there has been a distinct improvement in procedures for saving the feet. In the past, following the removal of a gangrenous or osteomyelitic toe, the diabetic patient returned after an interval for the amputation of another or even a far higher amputation. To overcome this Dr McKittrick has introduced a transmetatarsal type of operation by which all the toes are removed at one time, and by the use of a long plantar flap, a useful foot is obtained. The first operation was performed in March, 1944, and by May, 1946, it had been done in 75 cases. Of these, 11 were failures, largely because operations have been undertaken in more and more serious and complicated cases to learn the limitations of this type of surgery. Staphylococci were cultured from the wounds in 52 of the 75 cases, either in pure culture or in combination with other organisms.

MISCELLANEOUS CONSIDERATIONS

Diabetic Camps and Societies

A list of diabetic camps and diabetic societies was given in last year's progress report.²² I am happy to say that in the future this listing will be continued and amplified by the American Diabetes Association.

Publications

Diabetes Abstracts, published by the American Diabetes Association, in conjunction with Eli Lilly and Company, continues to be invaluable. All are

looking forward with anticipation to the publication of the *Proceedings* of the meeting held in Toronto last September when the Association joined with the University of Toronto for the celebration of the discovery of insulin by Banting and Best.

Insurance

Insurance of diabetic patients is now a *fait accompli*. A new life-expectancy table to replace that of 1938 is in process of compilation by the Metropolitan Life Insurance Company and Joslin. This is in part subsidized by the Diabetic Fund of the Boston Safe Deposit and Trust Company and by gifts to it for this purpose from two insurance companies.

under consideration. Perhaps Dr King will tell us about that later. Asthma at night may be a different kind of condition, but as I understand it, bronchial asthma can bother patients mostly at night.

Was the shortness of breath on exertion a sequel to the story of asthma such as we frequently see?

FIGURE 2

Was this a case of chronic bronchiectasis in a patient with asthma and shortness of breath on exertion, as well as at other times, due to pulmonary insufficiency and not to cardiac insufficiency? Or was the shortness of breath a cardiac symptom?

The swelling of the ankles indicates either myocardial failure or local stasis. We cannot tell at

this point whether the ankle swelling was equally bilateral. We must certainly think of the possibility of beginning heart failure. If due to beginning heart failure, did the swelling follow left ventricular failure, or was it primarily from right ventricular failure? The ankle swelling was thought to be of cardiac origin, for the patient took digitalis irregularly, for cyanosis as well as for the dyspnea.

He had auricular fibrillation, and of course with the history to this point one wonders about mitral stenosis. Since the left auricle was not large and since no murmurs were heard, we have some serious arguments against such a diagnosis.

He had increasing circulatory failure, probably myocardial in origin. I judge that from the age of seventeen until he was forty, when he began to have asthma, he had been quite well. Is that true? I believe that you know something about the history, Dr Sprague.

DR SPRAGUE: Yes, that is true.

DR WHITE: I assume that he was active and that he had never had high blood pressure.

DR SPRAGUE: That is so.

DR WHITE: "Physical examination revealed a florid, extremely cyanotic, obese, well developed man." That sentence has one important expression—that is, "extremely cyanotic." The degree of cyanosis was evidently impressive.

The wheeze is interesting. Was that due to pulmonary disease or pulmonary congestion from left ventricular failure? The description is not that usually seen with left ventricular failure and consequent pulmonary vascular engorgement.

The scleras were icteric. Did they become more definitely so, or did that remain a questionable sign?

DR SPRAGUE: They did not become more icteric.

DR WHITE: "The neck veins were full but not pulsating." That finding suggests considerable venous pressure and could go with the marked edema that the patient showed.

I assume that the large pulse deficit was due to the fact that the second and third beats of the bigeminy and trigeminy did not reach the wrist.

There were no murmurs. That statement should be underlined as being extremely important.

He showed evidence of hydrothorax, as well as a considerable amount of ascites. There is one sign not mentioned that I should like to ask about. Was there any clubbing of the fingers?

DR SPRAGUE: No.

DR WHITE: That is significant for certain reasons with reference to both the lungs and the heart. Certain kinds of congenital heart disease, particularly the tetralogy of Fallot, with considerable cyanosis and no pulmonary disease, are associated with clubbing, as is, of course, subacute bacterial endocarditis.

rate of about 120. The peripheral pulse was about 52. The heart sounds were loud, slapping at the apex and muffled in other areas. No murmurs could be heard when the patient was either reclining or sitting up. Examination of the chest revealed flatness and absent fremitus and breath sounds below the fourth interspace on the right posteriorly extending forward to the sternum at about the same interspace. A few moist inspiratory rales and soft expiratory rhonchi of the right lung were noted above this area. The left lung was clear except for a few moist rales at the base. The abdomen was much distended, moderately tense and revealed shifting dullness about half way up the flanks with a fluid wave. The liver could not be felt or balloted but was percussed three fingerbreadths below the costal margin. The spleen was not palpated but appeared slightly enlarged to percussion. The arm veins collapsed at a level about 10 cm above the sternum. There was severe pitting edema of both legs and the genitalia. A reducible left inguinal hernia extended into the scrotum. The blood pressure was 160 systolic, 80 diastolic.

Examination of the blood revealed a red-cell count of 5,520,000, with a hemoglobin of 17 gm, and a white-cell count of 8100, with a normal differential count. The urine had a specific gravity of 1.018 and gave a +++ test for albumin. The sediment contained a few hyaline and rare granular casts, a few red cells and 3 white cells per high-power field. The nonprotein nitrogen was 34 mg, and the total protein 7.1 gm per 100 cc. An x-ray film of the chest disclosed a large quantity of fluid in the right pleural cavity obscuring the right leaf of the diaphragm, the right border of the heart and the lower two thirds of the right lung field. There was a questionably small quantity of fluid in the left costophrenic angle, with an increase in the hilar shadows and prominence of the pulmonary vascular shadows. An electrocardiogram revealed auricular fibrillation at an average rate of 90 with frequent ventricular premature beats from different foci producing trigeminy in some places (Fig 2). There was a high degree of right-axis deviation. The T waves were low in Leads 1 and 2 and inverted in Lead 3, with a sagging ST segment in Lead 2. The T waves were low in Leads CF₁, CF₄ and CF₆, with deep S waves consistent with right-axis deviation.

A right thoracentesis yielded 1000 cc of clear yellow fluid, which greatly relieved the respiratory distress and on analysis contained 1.9 gm of protein, no white cells and 1129 red cells per cubic millimeter. The patient was given Purodigin and Digifolin. On the sixth hospital day about 30 cc of fluid tinged with bright-red blood was noted in the sputum, with increased cough. There was some boggy swelling, increased heat, redness and tenderness of the calf of the right leg that the patient admitted had been present for several weeks

but had recently subsided. No chest pain was noted. On the following day he appeared to have edema of the face and was drowsy, and a chest tap on the right again produced 1000 cc of clear amber fluid with a total protein of 3.8 gm, no white cells and 1100 red cells per cubic millimeter. On the eighth hospital day minimal right-calf tenderness was present, with only slight pitting edema. A surgical consultant believed that the calf tenderness and edema could be accounted for by heart failure and advised against vein interruption. Two days later, cyanosis was still noted. The patient refused any form of oxygen therapy. He did not prefer to sit upright in bed but lay almost always on the right side. Examination of the urine at that time revealed a + test for albumin with an occasional hyaline cast. The nonprotein nitrogen was 42 mg per 100 cc. By the fourteenth hospital day the cardiac rhythm had become normal. He continued, however, to have considerable chest fluid and ascites. Two days later, another 1000 cc of amber, slightly cloudy fluid was withdrawn from the right chest, 900 cc of similar fluid was taken from the abdomen. The chest fluid contained 1240 red cells and 90 white cells per cubic millimeter of which 70 per cent were polymorphonuclear cells. On the sixteenth day not much change had been noted. The heart sounds were surprisingly strong.

The patient had been refusing medication and continued to be markedly cyanotic. He had developed a decubital ulcer. On the following day another 1000 cc of fluid was removed from the right chest, and on the morning of the twentieth day he was again coughing up dark-red blood and appeared weak. The blood pressure was 100 systolic, 80 diastolic, and the pulse was about 80 radial and 100 apical. The lungs were essentially unchanged, and there was dullness on the right up to the level of the fifth or sixth rib posteriorly. On the following day he appeared still weaker. The blood pressure was 70 systolic, 50 diastolic. He became disoriented and finally unresponsive, with small convulsive jerks in the left arm and absent reflexes. Aminophyllin and continuous oxygen were without effect, and he finally died on the twenty-third hospital day.

DIFFERENTIAL DIAGNOSIS

DR PAUL D. WHITE. I am not at all sure whether any of the asthmatic attacks had anything to do with what followed. I wonder whether the patient had been studied particularly for this situation and whether we have any information about tests for allergy.

DR HOWARD B. SPRAGUE. He had not been tested.

DR WHITE. One wonders if the asthma was coincidental or part and parcel of the disease process.

DR WHITE The ectopic beats had disappeared, but the fibrillation may still have been present

DR SPRAGUE Yes, it was

DR WHITE The patient then showed a small pulse pressure, only 20 mm

This is certainly an unusual picture, and we must try to fit in several findings that are not often seen together. These are the years of asthma causing nocturnal orthopnea, the congestive heart failure, the deep cyanosis without finger clubbing, the auricular fibrillation (with many ectopic beats), the marked right-axis deviation apparent in the electrocardiogram, the absence of heart murmurs and the blood spitting. The last sign may have occurred terminally, there was no mention of early blood spitting.

One naturally thinks at once of the so-called "black cardiacs" or *cardiaques noirs* of Averza, or Averza's syndrome, which is more of a syndrome than a disease, in which the combination of pulmonary vascular disease and peripheral stasis secondary to right heart failure is responsible for the cyanosis. Bronchial asthma does not produce cyanosis, except in the rarest cases, of which I have not seen an example. I have always wondered if severe prolonged bronchial asthma might not come to us here, but the asthmatic patients that I have seen for years have not been cyanotic and have not died of heart failure.

Was this endarteritis obliterans (syphilitic, or more probably not)? We have not seen syphilitic endarteritis obliterans here. We have encountered endarteritis obliterans of the lungs, but so far as I know, it has been unexplained, so-called "idiopathic endarteritis." Periarteritis nodosa, or simply extensive fibrosis compressing or otherwise involving the arteries of the lung, must also be considered. Certainly, chronic cor pulmonale with final failure of the right heart is a strong probability. Can there have been not only terminal pulmonary infarction but also earlier repeated attacks in large part responsible for a chronic cor pulmonale? That is what we have seen here in rare cases — namely, attacks of repeated and extensive pulmonary embolism that can lead with survival to chronic cor pulmonale.

What else must one consider in the differential diagnosis? Could there have been mitral stenosis? That is possible, but I suppose that it is less likely than chronic cor pulmonale. To be sure, auricular fibrillation was present, but it should have set in years previously before failure developed rather than so late in life — the congestive failure came apparently before the auricular fibrillation.

DR BENJAMIN CASTLEMAN The patient was not examined at that time, and we do not know that the congestive failure was not present.

DR WHITE It was noted for a year but may have been present longer. Also, if there were enough mitral stenosis to produce such a clinical

picture as this, someone at some time should have heard a murmur. Although exceptions have been reported, I have never encountered a case of marked mitral stenosis without a murmur. Moreover, the left ventricular auricle was not large, and it looks as if there was too much right-axis deviation, although I have seen cases of this degree of right-axis deviation with mitral stenosis.

We must also consider congenital heart disease, but we do not know how long this patient had been cyanotic — probably not constantly since childhood, with this degree of cyanosis. The tetralogy of Fallot does not seem to be in keeping in this case, for this kind of history without clubbing of the fingers but with auricular fibrillation is not seen, so far as I know, in cases of tetralogy of Fallot. A large auricular septal defect is also a possibility — the patient was old for the tetralogy of Fallot, but not too old for an auricular septal defect, which may be almost symptomless until well into middle age. The strain of an overloaded pulmonary circulation can cause failure of the right side of the heart and death. Auricular fibrillation is a rare accompaniment of congenital heart disease but a possible complication in Lutembacher's disease, which consists of the combination of an auricular septal defect and mitral stenosis.

Then there are the rare conditions that should be thought of in any difficult case: tumors involving the heart, malignant or benign, for which we have no clue in this case, a mediastinal tumor compressing the pulmonary artery, and unusual infestation by parasites, which so far as I know does not produce such a picture as this except in dogs with filariasis involving the right heart and pulmonary arteries that causes a subacute cor pulmonale from plugging of the pulmonary arteries and right ventricle by the filarial parasites themselves. Malnutrition (beriberi), poisoning, endocrinopathy and myocarditis or other involvement of the right ventricle of unknown cause are some of the other rare conditions that should be thought of but not diagnosed in this case. Hypertension and atherosclerosis which primarily involve the left ventricle, do not fit, nor does thyroid disease or syphilitic aortitis, unless there was a bizarre, almost unique aneurysm of the ascending aorta compressing the pulmonary artery and causing a chronic cor pulmonale, of which we have seen a few cases. Constrictive pericarditis also seems to be out.

My diagnosis therefore rests between chronic cor pulmonale due to pulmonary endarteritis obliterans or to repeated pulmonary embolism or thrombosis with right ventricular failure and, second best, a congenital auricular septal defect, with or without mitral stenosis (Lutembacher's disease), which we are unable to diagnose because of the absence of a murmur, with failure of the right side of the heart, in either case complicated by digitalis toxicity and terminal pulmonary infarction. I am torn between

The blood studies did not indicate a polycythemia. That is important.

The urinary findings could have been due to renal congestion alone.

We must look into the degree of enlargement of the lung hilar shadows, the size of the left auricle and the condition of the mediastinum. May we see the x-ray films?

DR RICHARD SCHATZKI: We have only these two films taken at the time mentioned in the record. The large amount of fluid on the right side can be seen. It obscures completely the right border of the heart, which is unfortunate. From the film alone I am not sure that there was fluid in the left pleural cavity. The left lung is fairly large. Of what we can see of the pulmonary vessels the ones on the left side are almost completely obliterated but show some distention, which is also visible in the lateral view. The pulmonary conus is slightly prominent. The apex of the heart reaches farther to the left than normal. How much of that is due to enlargement of the heart and how much to displacement of the heart by the fluid is difficult to say from the film at hand.

DR WHITE: The heart was not so large as I thought from the earlier description on physical examination, but I suppose that there may have been some change at that time. There was still a moderate amount of space between the left border of the heart and the left chest wall. It was not one of the enormous hearts that one sees in mitral stenosis, in which the heart nearly fills the chest. Do you see any scars of pulmonary infarction?

DR SCHATZKI: Not in the small amount of lung that I can see.

DR WHITE: Is anything wrong with the aorta?

DR SCHATZKI: I can see just the edge of the arch of the aorta, and that is of approximately normal size for a patient of this age.

DR WHITE: The trachea is not particularly deviated?

DR SCHATZKI: It is normal in position.

DR WHITE: It is always unsatisfactory, for me at any rate, to read interpretations of electrocardiograms without seeing the actual film or print, just as it is with an x-ray film. Even without my asking, these electrocardiographic films were sent to me, so that I have a fair idea of the moderately high degree of right-axis deviation. It is not so marked as one sees with the tetralogy of Fallot. It is consistent with two or three other conditions. I think that generally we see a higher degree of right-axis deviation, including prominence of the S waves in the precordial leads with an auricular septal defect, although we have occasionally seen as much as this with a cor pulmonale. With mitral stenosis a moderate degree of right-axis deviation is occasionally found. The ventricular rate was rapid, — nearly 140, — so that that could have increased the degree of heart failure at the time, and it

looked as if there was considerable sagging of the ST segments, suggesting digitalis effect, although one would expect a lower rate if there had been a high degree of digitalis effect. That was the first film. There is a second tracing, described in the record, showing ectopic beats and producing a bigeminy and trigeminy. The usual ventricular complexes look much the same, and auricular fibrillation is present as in the first record, but we have an important change: the trigeminal ectopic beats alternate in appearance and move in opposite directions (Fig 2). This occurs regularly throughout the tracing, one might almost label it the beginning of paroxysmal ventricular tachycardia with beats alternating in direction. This is considered an unfavorable sign — an indication of toxicity close to that due to a fatal dose of digitalis. Was much digitalis being given at that time, Dr Sprague?

DR SPRAGUE: That is the rhythm with which the patient entered the hospital. The digitalis had been given outside and was omitted temporarily after admission, that did away with the toxic rhythm. The first electrocardiogram was taken a year previously.

DR WHITE: This unusual rhythm could have been the result of serious digitalis intoxication, but we have seen it in other extremely ill patients. Such irritability of the heart tends to lead to ventricular tachycardia and fibrillation and death.

What was the blood Hinton or Wassermann reaction?

DR SPRAGUE: It was negative.

DR WHITE: The electrocardiogram points strongly to marked enlargement of the right ventricle and is not the pattern of coronary heart disease, in which an inverted QRS wave in Lead I occasionally occurs. The QRS waves are narrow and are in keeping with right ventricular enlargement predominantly, rather than with coronary heart disease. One wonders if there was any suggestion of neoplastic disease in the thorax, for the fluid contained blood, but it was not the typical bloody fluid that one sees with neoplasm. I wonder how the Purodigin was given. Was it administered outside, and was there an interval before he received it again in the hospital?

DR FREDERIC C GOETZ: He refused medication for several days and was then given Digifolin intramuscularly.

DR WHITE: The patient then had what seemed like a thrombosis of the leg, with pulmonary infarction as a complicating factor.

"By the fourteenth hospital day the cardiac rhythm had become normal." Was that true according to the electrocardiogram, or thought to be true?

DR SPRAGUE: It was less irregular after the disappearance of the toxic rhythm.

DR WHITE In this case, if I had relied on the electrocardiogram alone, I would have made the correct diagnosis, since almost nothing other than considerable mitral stenosis of long standing can give rise to a pattern like this — namely, the combination of right-axis deviation and auricular fibrillation. The possibility of considerable mitral stenosis, however, with no murmur at all, little enlargement of the left auricle evident fluoroscopically and a high degree of cyanosis seemed even more exceptional, and I therefore chose to consider the electrocardiographic pattern as an exception to the rule. This case has stimulated us to investigate the relative rarities of these various exceptions

CASE 33132

PRESENTATION OF CASE

First admission A thirty-seven-year-old machinist entered the hospital because of a generalized rash, malaise and sore throat

Two months before admission and eight days after promiscuous kissing at a party a nontender lesion similar to a cold sore developed on the right lower lip. A succession of three lesions then appeared on the chin. A physician treated them with boric acid salve without improvement, another physician gave him penicillin salve after which the sores dried somewhat, but they never healed. A week before admission the patient developed a generalized rash with much malaise, sore throat and swelling of the lymph nodes in the neck.

Physical examination showed a generalized maculopapular eruption, mucous patches over the hard palate and cervical lymph-node enlargement. Colonies of *Treponema pallidum* were identified on dark-field examination of the lesion on the lip. The blood Wassermann reaction was positive. The patient was treated with 2,400,000 units of penicillin over a period of seven and a half days. The eruptions faded and he was discharged.

Final admission (eleven months later) Following discharge the patient was seen frequently in the Out Patient Department. No further treatment was carried out. The blood Hinton and Wassermann tests became negative in the course of several months, and he was symptom free until two months before admission. At that time he began to have attacks of headache, dizziness and a sense of burning and obstruction of the nose that were thought to be brought on by acid fumes inhaled from a soldering process at work, although they were admitted to have occurred on the street without apparent instigating cause. A month before admission there were several episodes of chills followed by nausea. The patient had visual hallucinations at work, seeing people in places where he knew they could not be. He had been drinking heavily, owing to worry about his illness. The visual hallucina-

tions ceased when he stopped drinking, but the other symptoms persisted. The headaches increased, centering especially just above the eyes. A week before admission he began to vomit occasionally, and the headache was so severe that sleep was impossible.

Physical examination disclosed a slightly disoriented patient complaining of photophobia and constantly rubbing his eyes. The abnormal physical findings were limited to the neurologic examination. There was moderate to marked tenderness over the right frontal sinus and antrum. The neck was not stiff. Odor perception was markedly impaired but not absent on the right, and was normal on the left, the air passages were not obstructed, nor was there any nasal discharge. Visual acuity on the right was 20/40, and on the left 20/50. The right pupil measured 3 mm, and the left 2 mm, both reacted slightly to light but not to accommodation. There was a completely congruous left homonymous hemianopsia with splitting of the macula lutea. The extraocular movements and the fundi were normal. The rest of the cranial nerves were normal. The left arm and leg were weak. The tendon reflexes were normal and equal on both sides. There was no ankle clonus. Pain, touch, position and vibration perceptions were normal.

The temperature was 99°F, the pulse 76, and the respirations 20. The blood pressure was 120 systolic, 80 diastolic.

The red-cell and white-cell counts and the hemoglobin were normal, and examination of the urine was negative. On lumbar puncture the initial spinal-fluid pressure was equivalent to 150 mm of water. The fluid was clear and contained 94 lymphocytes, 0 neutrophils and 0 red cells per cubic millimeter, the total protein was 125 gm, and the chloride 122 mg per 100 cc, the gold-sol curve was 0112223322. Two blood and spinal-fluid Hinton tests were negative. X-ray films of the skull and sinuses showed no erosion of the cribriform plate or other abnormalities. The electrocardiogram was "within normal limits" except for rather questionable disturbances on the right side, especially anteriorly toward the midline.

While in the hospital, the patient complained constantly of pain in the right frontal region and behind the right eye. Burning sensations in the right side of the nose occurred frequently. The hemiparesis and hemianopsia persisted. Lymphocytes were found on repeated lumbar puncture, and the spinal-fluid protein remained elevated. An operation was performed on the eighteenth hospital day.

DIFFERENTIAL DIAGNOSIS

DR G COLKET CANER It seems to me that at the second entry the question that probably first preoccupied the house staff was whether the patient's symptoms were due to syphilis. He had had

these two interpretations I think that I favor the first, — namely, a chronic cor pulmonale, — but I would not be surprised to find the second, or indeed something else

DR SPRAGUE It is reassuring to have Dr White argue the same way as we did in this case I saw the patient only when he was extremely ill in the hospital Routine electrocardiograms were sent to the laboratory, and Dr Williams interpreted them as consistent with rheumatic heart disease He found that the house officer in requesting the electrocardiogram had made the diagnosis of rheumatic heart disease He then remembered that he had seen this patient a year before, when he was ambulatory and rapidly fibrillating prior to digitalization I asked him to examine the patient again We listened closely for a mitral diastolic murmur, but we were unable to hear it Knowing that the patient had been examined previously when not in extremis, we thought that we had further evidence that he did not have mitral stenosis In retrospect the one thing that we should have put more emphasis on and that I had put in my notes was that the first heart sound in this man remained louder, or at any rate of better quality, than he should have had when he was so sick

DR WHITE That makes me turn a little more toward mitral stenosis

DR SPRAGUE The heart sound was noted as loud by Dr Goetz, who said that the patient had mitral stenosis

DR DONALD S KING I thought from the history that this was not bronchial asthma The illness sounded circulatory to me

DR WHITE Do you usually find an exaggeration of symptoms in bronchial asthma at night?

DR KING Not as the history is given here It suggests mitral stenosis

DR CONGER WILLIAMS I should like to say that the cyanosis was the thing that led most of us to discard the diagnosis of mitral stenosis in favor of chronic pulmonary disease We did not believe that it was straight bronchial asthma but thought that it was possibly a lung condition, pulmonary fibrosis or something of that sort

DR SPRAGUE We thought that the patient might have had thrombosis of the pulmonary artery

DR ISAAC TAYLOR One striking thing on listening to the lungs was the severe prolongation of expiration, which persisted until the end and became marked

CLINICAL DIAGNOSES

Cor pulmonale
Pulmonary fibrosis and emphysema
Pulmonary infarcts

DR WHITE'S DIAGNOSES

Cor pulmonale, with congestive heart failure and auricular fibrillation or auricular septal de-

fect, with or without mitral stenosis (Lutembacher's disease)

Pulmonary infarction (terminal)

Digitalis intoxication

ANATOMICAL DIAGNOSES

Rheumatic heart disease, with severe mitral stenosis,

Cardiac hypertrophy, marked, right ventricle

Pulmonary infarct

Endocarditis, chronic rheumatic, slight, aortic and tricuspid

Cardiac and portal cirrhosis

Pulmonary emphysema, slight

Anasarca

PATHOLOGICAL DISCUSSION

DR CASTLEMAN We found 6000 or 7000 cc of fluid in the abdomen and a similar amount of fluid in the right chest There was none in the left pleural cavity In the apex of the right lower lobe there was an infarct that measured about 4 or 5 cm in diameter but no other infarct in the right lung and none in the left lung

DR WHITE Was there any suggestion of old scars in the lungs — that is, of infarcts?

DR CASTLEMAN No, the heart was large, weighing almost 700 gm The right ventricular wall was thick, measuring 1 cm, about three times the normal size The left ventricle measured 16 mm in thickness The tricuspid valve ring was markedly dilated, measuring almost 16 cm in diameter, and there was slight thickening and shortening of the chordae tendineae of one leaflet The dilatation of the right auricle was tremendous, measuring in one diameter about 14 cm We were unable to find any opening between the right and left auricles The mitral orifice was merely a rigid slit measuring 1 cm long and about 0.5 cm in its greatest diameter The valve was thickened and extensively calcified The left auricle was large and thick The aortic cusps showed some interadherence, but not enough to produce any appreciable stenosis There was therefore severe mitral stenosis and only minimal rheumatic involvement of the aortic and tricuspid valves

There was evidence of generalized chronic passive congestion The liver was somewhat large and was quite cirrhotic On microscopical examination, I believe that there was a combination of both cardiac and portal cirrhosis

DR WHITE The history of the auricular fibrillation is important in the absence of the murmur of mitral stenosis

DR CASTLEMAN There was a mural thrombus of the right auricle, which was probably the source of the pulmonary embolus, since the leg veins were free from thrombi Although the lungs showed some emphysema, I believe that mitral stenosis was responsible for the right-sided cardiac hypertrophy

not lay much stress on the lack of pupillary reaction to accommodation

A tumor at the base of the brain fairly often gives a number of lymphocytes in the spinal fluid, so that such a location would go with the spinal-fluid findings. A tumor in this region would not have to be large to cause the signs and symptoms presented, and a small tumor might account for the fact that the spinal-fluid pressure was not high.

Another possible location is the temporoparietal lobe, but a tumor there would have to be large to give a complete homonymous hemianopsia with splitting of the macula because the macular fibers in this portion of the optic radiations are well spread out. But a large tumor seems somewhat unlikely because of the localized headache and the low spinal-fluid pressure.

It therefore seems to me that the likeliest diagnosis is a tumor at the base of the brain involving the right optic tract and causing pressure on the spinal tract in the cerebral peduncle. I remember a case some years ago of a cholesteatoma in this region, but that is an unusual tumor, and I am not definite about the type of tumor in the case under discussion.

I am not sure enough of the location to suggest operation without a ventriculogram, and I imagine that that was done as part of the operation.

DR CHARLES S KUBIK Dr Rose, would you like to comment?

DR AUGUSTUS S ROSE I was on duty at the time the patient was admitted to the Neurological Service, and I might say that we went through the same type of reasoning as Dr Caner. As always, however, when the patient is seen one gets quite a different impression from that obtained on mere reading of the protocol. The first diagnosis that we considered was syphilitic meningitis. As was said at the time the proper diagnosis was made, a similar case would lead to a similar mistake. In other words, when a man who has had early syphilis adequately treated or presumably treated adequately and less than a year later develops headaches and lymphocytes in the spinal fluid, the case is syphilitic meningitis until proved otherwise. On the other hand this man was drowsy on admission. That was not emphasized in the record, and the history of alcoholism was somewhat more than is indicated. Subdural hematoma was our second diagnostic consideration, and yet the homonymous hemianopsia was against that. Finally, surgery became inevitable.

DR KUBIK As Dr Caner suggested, this patient had a ventriculogram before he was operated on. I suppose we might see the films now.

DR MILFORD SCHULZ These are rather representative films. One can see the entire ventricular system, somewhat increased in size and displaced to the left, the third ventricle as well as both lateral ventricles. The right lateral ventricle is pushed or displaced beneath the tentorium. The lateral view

is not helpful. The anteroposterior view seems to be the most useful and indicates a large space-occupying lesion in the right hemisphere, probably in the temporoparietal region.

CLINICAL DIAGNOSIS

Syphilitic meningitis?

Subdural hematoma?

DR CANER'S DIAGNOSIS

Brain tumor, type undetermined

ANATOMICAL DIAGNOSIS

Glioblastoma multiforme, right temporal lobe

PATHOLOGICAL DISCUSSION

DR KUBIK A right temporal-lobe tumor was found at operation. Biopsy diagnosis at operation indicated that it was glioblastoma multiforme, and no attempt was made to remove it. The patient remained in coma and died on the third or fourth postoperative day.

DR LEWIS K DAHL May I ask if the symptoms that Dr Caner interpreted as evidence of fifth-nerve involvement might not have represented attacks of uncinat epilepsy?

DR ROSE I might say in that connection that before operation the sensations that the patient called pain were thought to be attacks of uncinat epilepsy.

DR KUBIK Lantern slides of serial coronal sections of the brain showed a tumor in the lower medial portion of the right temporal lobe. The cut surface had the necrotic grayish-yellow appearance that is characteristic of a glioblastoma multiforme. The tumor was in close relation to the third nerve, and it is rather surprising that there was not more evidence of third-nerve involvement than a slightly enlarged pupil. Its close proximity to the cortical spinal tract in the cerebral peduncle probably accounted for the hemiparesis, and the involvement of the optic tract lateral to the peduncle explained the homonymous hemianopsia. An interesting feature was the invasion of all the subependymal tissues outside the lateral ventricles by tumor. Histologically, the tumor was a glioblastoma multiforme. In many places there was infiltration of the subarachnoid space with a few plasma cells. There was some perivascular lymphocytic infiltration in the medulla. The cellular infiltration at a distance from the tumor, taken in connection with the history, was suggestive of syphilis.

DR JAMES A MEATH In answer to Dr Dahl's question, I would like to say that it was because this patient had attacks of uncinat epilepsy that he was treated on the Neurological Service. The symptom of difficulty in smelling was also possibly due to the tumor.

DR KUBIK The tumor invaded the uncinat gyrus and so created a condition in which attacks of uncinat epilepsy might have occurred.

primary and secondary syphilis about a year previously, and the treatment given at that time is generally considered to be the minimal adequate penicillin treatment in early secondary syphilis. Dr. Rose tells me that such treatment can be expected to give a cure in a high percentage of cases but that at present a course of bismuth injections would undoubtedly be given at the same time. The fact that the blood Hinton test changed to negative indicates that the treatment was probably adequate in this case. But we have no spinal-fluid examination, and in a case with secondary syphilis a spinal-fluid examination ought to be made six months after treatment and again a year later because during the secondary stage of syphilis the central nervous system is invaded and one cannot be sure that treatment adequate to change the blood Wassermann and Hinton reactions to negative will also be adequate to eradicate the infection from the nervous system. In this case there was no spinal-fluid examination prior to the second entry so that the staff could not have been entirely sure that the treatment given had been adequate.

Irrespective of whether the patient's syphilis was treated adequately there is evidence that the patient himself was not treated adequately because he apparently worried so much about his illness that he began drinking heavily. It is, of course, important not only to treat the illness but also to treat the patient. In particular the patient should be helped to take his illness well and to react well also to other things in his life that might be upsetting to him. The physician can often contribute more in this direction than he can in treating a disease itself.

Going back to whether or not the patient's symptoms were due to syphilis, although the spinal-fluid examination showed a number of changes characteristic of syphilis, — namely the high lymphocyte count, the high total protein and the change in the gold-sol curve, — there were two negative spinal-fluid Hinton tests. Sometimes in syphilitic meningitis the Hinton test is negative at the first spinal puncture but at the second puncture the test is almost always positive. In a syphilitic meningitis, the blood Hinton reaction is also almost always positive, and the fact that there were two negative blood Hinton tests is also strong evidence against syphilis. Additional evidence against syphilis is the fact that the total protein was higher than one would expect with this lymphocyte count, if the count were due to syphilis. A count of 94 lymphocytes per cubic millimeter due to syphilis would be accompanied by a total protein of 55 or 60 rather than one of 125 gm per 100 cc. It is also hard to explain the homonymous hemianopsia on the basis of meningovascular syphilis or of syphilitic meningitis. A syphilitic meningitis would also cause a stiff neck and a generalized headache, whereas this man's headache was fairly well limited to the orbital

region and to the supraorbital and infraorbital regions. For all these reasons I think that syphilis can be ruled out.

If syphilis is not the diagnosis, what else could have caused the spinal-fluid findings? As possibilities one might think of poliomyelitis and multiple sclerosis, but obviously the history does not suggest either diagnosis. One thinks also of brain abscess, but in brain abscess one would expect a number of neutrophils in the spinal fluid in addition to the lymphocytes. Also, the total protein was rather high in comparison to the number of cells for brain abscess. I therefore think that brain abscess is unlikely, too.

Then one comes to tumor, and it seems to me that tumor is the likeliest diagnosis. Tumor, of course, frequently gives a high protein and with the high protein there can be changes in the gold-sol curve. Tumor does not often cause such a high lymphocyte count in the spinal fluid, but it may do so and when it does polymorphonuclear leukocytes are usually present in addition to the lymphocytes. But sometimes the increased count in the spinal fluid is limited to lymphocytes, as in this case.

If the spinal-fluid changes were due to tumor, where was the tumor located? It seems to me that the most definite finding that we have to go on is the homonymous hemianopsia with splitting of the macula, which is usually caused by a lesion located where the macular fibers are well bunched, they are well bunched either at the extreme posterior part of the occipital lobe or in the optic tract. If the lesion had been in the extreme posterior part of the occipital lobe it seems to me that it would be hard to explain the left hemiparesis, and the dilated right pupil would also be hard to explain in the absence of marked pressure. It would perhaps be possible to account for the fact that the headache was centered in the back of the orbit because the tentorium is innervated by the fifth nerve and sometimes pressure on the tentorium causes referred pain to the back of the orbit. If, however, the tumor were located at the base of the brain involving the right optic tract and causing pressure on the right cerebral peduncle it could readily explain the picture. A lesion there could involve the third nerve, causing a slightly dilated pupil, it could also involve the trigeminal nerve and give rise to extreme pain in the orbit and in the supraorbital and infraorbital regions and perhaps to the stinging pain in the nose. A lesion in this region would not account for the failure of the pupils to react to accommodation, but this finding is hard to explain by any lesion that would also cause a homonymous hemianopsia. Patients often do not try to focus the eyes on a finger held close to their eyes, however, and if they do not there is no reaction to accommodation. To get patients to focus one may have to ask them, for instance, to tell the time by looking at a watch held close to the eyes. I therefore do

THE "VOLUNTARY HOSPITAL"

ONE of the more important talks presented at the Massachusetts General Hospital's Ether Day Centenary last October was that of Dr. Nathaniel W. Faxon, director of the hospital, entitled "The Voluntary Hospital — How Can It Survive in the Modern World?" This paper, which is published elsewhere in this issue of the *Journal*, merits particular attention because it concerns us all, doctor and layman alike.

The term "voluntary hospital" is applied to non-profit, nonpolitical institutions, praiseworthy common in this country, that have been established as philanthropic organizations, designed for the common good. As leaders in their field from the start, they have set the pace and made the advances. That the Massachusetts General Hospital should be a leader and a pioneer among the hospitals of this type is purely circumstantial, it does not affect the point of Dr. Faxon's argument.

The point is that the question of the survival of the voluntary hospital is now before us to be answered, and that question applies particularly to the most valuable and consequently the most costly of these institutions — the hospital that adds to its service of caring for the sick the services also of scientific research and of training medical, nursing and technical personnel.

The high cost of dispensing these services has always been met, precariously, by two sources of income. The lesser of these has been the payment for services from patients and from agencies responsible for patients. The greater and more important has been derived from the gifts received perennially from well-to-do and philanthropically minded persons. As a result of increased taxation and decreased available incomes, the latter vital revenue is drying up at the source. The will may still be present, but, to make practical a familiar quotation, the giver without the gift is bare.

An actual injustice generally prevails, moreover whenever third parties enter into the contract between hospital and patient — state, city and town departments of welfare, a variety of federal agencies and the insurance companies operating under workmen's compensation acts. None of these, so far as we can say at the moment, despite their avowed

commitments, have ever met their financial responsibilities in full. The deficits that they leave have to be met by hospital funds, sometimes from principal and sometimes from the revenue derived from community-chest allotments. It should be as much a source of shame as it is of sorrow that the insurance companies and the governmental agencies are willing to rely for the fulfillment of their contracts on the meager funds of charitable hospitals.

Since hospitals can no longer continue to make up the difference between the costs of caring for patients and the part of the costs that governmental and other agencies have so far been willing to discharge, and since the better hospitals are loath to settle for less expensive and lower grade care for such beneficiaries, it seems high time that these agencies prepared themselves to pay in this respect full price for what they are receiving.

MASSACHUSETTS MEDICAL SOCIETY

TREASURER'S REPORT COVERING REFUND DISTRIBUTION

The Treasurer of the Massachusetts Medical Society makes the following report regarding the refund to district societies for 1947:

The Council voted to distribute the sum of \$4000 to district societies. The total number of payments of annual dues received by the Treasurer by March 1, to be counted for the refund, was 4527. Therefore, the refund to the district societies for each paid fellow is \$0.8836.

The following table gives the number of payments, as of March 1, and the refund to each district as of March 17:

DISTRICT	NUMBER	REPORTED	PAID	REFUND
Barnstable	44			38.88
Berkshire	127			112.21
Bristol North	66			58.31
Bristol South	181			159.93
Essex North	175			154.63
Essex South	261			230.62
Franklin	40			35.34
Hampden	301			265.96
Hampshire	64			56.55
Middlesex East	135			119.28
Middlesex North	114			100.73
Middlesex South	918			811.14
Norfolk	818			722.78
Norfolk South	138			121.93
Plymouth	130			114.87
Suffolk	566			500.11
Worcester	367			324.28
Worcester North	82			72.45
	4527			\$4000.00

In 1946, for comparison, the total number of payments for the refund was 3965.

CANCER MONTH

THE designation of April as Cancer Month is assuming greater significance each year. As *Cancer Facts*, a pamphlet published a year ago by the Metropolitan Life Insurance Company, points out, the cancer death rate per 100,000 population increased from 64.0 in 1900 to 120.3 in 1940. This does not necessarily mean that cancer in any particular age group is becoming more prevalent, but it does indicate that the percentage of persons in the older age groups has markedly increased and that there has been an improvement in diagnostic procedures. In 1943, cancer was the most frequent cause of death in women thirty-five to fifty-four years old, and the second most frequent in those fifty-five to seventy-four, it was second in men from forty-five to seventy-four. Death rates are highest in the large cities, and lowest in rural areas, which merely points out that

more cases are diagnosed in places where adequate medical facilities are widely available. In women, approximately 40 per cent of cancers occur in the digestive tract, and a like percentage in the genital organs, including the breasts. In men, more than 50 per cent of cancers are found in the digestive tract, with about 20 per cent in the genitourinary tract and over 10 per cent in the lungs. Among the industrial policyholders of the Metropolitan Life Insurance Company, there has been a steadily increasing downward trend in cancer deaths among women, and there has even been a slight drop among men in recent years.

All these facts serve to emphasize the need for the early diagnosis of cancer, and its prompt treatment. It is well known that at least 80 per cent of women with breast cancer can be cured if a radical operation is performed before the malignant growth has spread to the axilla through the lymphatic vessels. That a "lump" in the breast is easily recognizable by the patient and that women have become increasingly aware of the significance of such a lump are undoubtedly largely responsible for the decrease in deaths from cancer among women, but many cures of cancer in other locations could be effected if the persons could be educated to undergo semiannual or annual physical examinations and also to go to a physician when certain symptoms are experienced.

In the past, cancer education by state departments of health and by organizations such as the American Cancer Society has been chiefly directed to the public. It is becoming more and more apparent, however, that the general practitioner and other physicians who see relatively few cases of cancer each year should be kept well informed concerning the most recent advances in diagnosis. For this reason the American Cancer Society has decided to issue a monthly publication *Cancer*, which will be sent to all practicing physicians in the United States. In this way it is hoped that physicians will become increasingly aware of symptoms that suggest cancer, that their patients will be warned concerning the need for reporting such symptoms, that all such cases will be referred, if necessary, to someone properly qualified to make the diagnosis and to give treatment and that the number of deaths due to cancer will markedly decrease.

THE PROBLEM OF SOCIAL MEDICINE: EQUILIBRATING THE DISTRIBUTION AND TECHNOLOGY OF MEDICAL CARE*

WINSLOW CARLTON

NEW YORK CITY

NO SUBJECT calls more insistently than social medicine for a disclaimer of omniscience. Medicine as a social institution is peculiarly complex both in structure and in function. This paper essaysonly to indicate the nature of a central problem and to suggest a few principles for guidance toward solution.

Throughout the United States today, one element in the distribution of medical care is under sharp attack. Strong political forces are pressing for a new way of paying for medical services. On the principle that all people have an equal right to the benefits of medicine, it is proposed that the Government cover the costs. Although many opponents believe that the movement "to socialize" medicine, as the attempt has been labeled, reflects no more than the desires of a small but vocal radical group, there is substantial evidence that the prevailing system for distributing medical care is not, in fact, appropriate to the technology of medicine.

To put it bluntly, the present system does not succeed in delivering to most people anything like the scope and quality of services of which modern medicine is capable. Formal sociologic studies conducted over the past thirty years provide statistical evidence in support of that conclusion, and observation of medical conditions in a variety of communities confirms it. There is no need to enumerate the quantitative findings; the principal ones have been conveniently assembled in a publication of the Social Security Board entitled "Medical Care and Costs in Relation to Family Income." What should be said is that these statistics require interpretation in the light of clinical observations. Without a knowledge of how medicine, as a social organism, actually functions, it is easy to conclude that a great deal of money collected and disbursed by the community at large will effect a cure.

Observation of conditions in New York City leads, I believe, to substantial modification of that con-

clusion. There it is true, are most of the medical prerequisites although it could do with more of almost everything, New York is rich in medical resources compared with many other communities. It must be added that the impressions recorded below have been distilled from the experience of eight years' effort to establish a voluntary system of prepayment for medical care in New York City.

The undertaking offers considerable advantages for purposes of observation, since such prepayment plans deal with both the suppliers and the recipients of medical and allied services. Enterprisers in this field—they might be called "adventurers" if one had a mind to, and many doctors have—are necessarily observers of how medicine actually works. One sees physicians in practice and learns what they expect of medicine and what they realize, concurrently, the patients disclose what they expect of medicine, how they go about getting it and what they get.

* * *

Our first conclusion is that nearly half the cases of illness occurring among New Yorkers of average income do not reach a physician or any other person of medical experience. With our wealth of resources,—including physicians, hospitals, clinics and social services,—virtually all emergency cases receive medical attention. No such statement, however, can be made about other illnesses. The evidence for this conclusion comes from experience with a prepayment plan operated by Group Health Insurance from 1938 to 1944 that was almost identical in scope of services with that of Boston's recent White Cross plan. It covered virtually all types of physician's care. Any licensed physician was eligible to participate, and a panel of three hundred and fifty general practitioners and a hundred and fifty specialists was developed. The maximum number of subscribers enrolled at any one time never exceeded fifteen hundred. The plan, obviously enough, was not a practical success, but something was learned about the existence of un-

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Chemistry of Anesthesia By John Adriani, M.D., director, Department of Anesthesia, Charity Hospital of Louisiana at New Orleans, and clinical professor of surgery, Louisiana State University of Medicine. 8°, cloth, 535 pp., with 45 illustrations. Springfield, Illinois: Charles C. Thomas, 1946. \$7.00.

Diagnostic Examination of the Eye. Step-by-step procedure By Conrad Berens, M.D., professor of clinical ophthalmology, Columbia University, executive eye surgeon, New York Eye and Ear Infirmary, and managing director, The Ophthalmological Foundation, and Joshua Zuckerman, M.D., C.M., instructor in ophthalmology, New York Eye and Ear Infirmary and Columbia Postgraduate School, ophthalmic surgeon, Midtown Hospital, and assistant ophthalmic surgeon, New York Eye and Ear Infirmary. 8°, cloth, 711 pp., with 410 illustrations. Philadelphia: J. B. Lippincott Company, 1946. \$15.00.

It's How You Take It By G. Colket Caner, M.D., associate in neurology, Massachusetts General Hospital, and psychiatrist in the Department of Hygiene, Harvard University. 12°, cloth, 152 pp. New York: Coward-McCann, Incorporated, 1946. \$2.00.

Diseases of the Retina By Herman Elwyn, M.D., senior assistant surgeon, New York Eye and Ear Infirmary. 8°, cloth, 587 pp., with 170 illustrations. Philadelphia: Blakiston Company, 1946. \$10.00.

Roentgen Diagnosis of Diseases of the Gastrointestinal Tract By John T. Farrell, Jr., M.D., clinical professor of radiology, Graduate School of Medicine, University of Pennsylvania, radiologist, Hermann Hessenbruch Memorial Department of Radiology, Lankenau Hospital, radiologist, Children's Hospital of the Mary J. Drexel Home, roentgenologist, White Haven Sanatorium, consulting roentgenologist, Frederick Douglass Memorial Hospital, and consulting roentgenologist, Mercy Hospital. 8°, cloth, 271 pp., with 190 illustrations. Springfield, Illinois: Charles C. Thomas, 1946. \$5.50.

Sex Problems of the Returned Veteran By Howard Kitching, M.D. With a foreword by Ernest R. Groves, professor of sociology, University of North Carolina. 12°, cloth, 124 pp. New York: Emerson Books, Incorporated, 1946. \$1.50.

Music in Medicine By Sidney Licht, M.D. 8°, cloth, 132 pp. Boston: New England Conservatory of Music, 1946. \$3.00.

Agnosia, Apraxia, Aphasia. Their value in cerebral localization By J. M. Nielsen, M.D., associate clinical professor of medicine (neurology), University of Southern California, and senior attending physician in neurology and assistant in neuropathology, Los Angeles County Hospital. Second edition, completely revised. 8°, cloth, 292 pp., with 59 illustrations. New York: Paul B. Hoeber, Incorporated, 1946. \$5.00.

Human Embryology By Bradley M. Patten, M.A., Ph.D., professor of anatomy, University of Michigan. School. 8°, cloth, 776 pp., with 446 illustrations. Philadelphia: Blakiston Company, 1946. \$7.00.

Hippocratic Wisdom. For him who wishes to pursue properly the science of medicine. A modern appreciation of ancient scientific achievement By William F. Petersen, M.D., Chicago. 8°, cloth, 263 pp. Springfield, Illinois: Charles C. Thomas, 1946. \$5.00.

Clinical Roentgenology of the Heart By John B. Schwedel, M.D., associate attending physician, Medical Division, and adjunct attending physician, Department of Roentgenology, Montefiore Hospital, New York City, and attending electrocardiographer and associate visiting physician in medicine, Gouverneur Hospital, New York City. *Annals of Roentgenology*, Vol. XVIII. 749 illustrations. New York: Paul B. Hoeber, Incorporated, 1946. \$12.00.

Diseases of the Adrenals By Louis J. Soffer, M.D., adjunct attending physician, Mount Sinai Hospital, New York City. 8°, cloth, 304 pp., with 42 illustrations and 2 colored plates. Philadelphia: Lea and Febiger, 1946. \$5.50.

Ophthalmology in the War Years Edited by Meyer Wiener, M.D., professor of clinical ophthalmology, Washington University School of Medicine. Volume I (1940-1943). 8°, cloth, 1166 pp. Chicago: Year Book Publishers, Incorporated, 1946. \$13.50.

NOTICES

SUFFOLK CENSORS' MEETING

The Censors of the Suffolk District Medical Society will meet for the examination of candidates at the Boston Medical Library, 8 Fenway, on Thursday, May 1, at 4:00 p.m.

NEW ENGLAND OBSTETRICAL AND GYNECOLOGICAL SOCIETY

The spring meeting of the New England Obstetrical and Gynecological Society will be held in Providence on Wednesday, April 30. Clinics will be held at the Rhode Island Hospital and the Providence Lying-in Hospital. Dinner will be served at the Squantum Club.

(Notices continued on page xxiii)

from which his profession sprang. He cannot be merely the technician, processing each patient who appears before him on the production line.

A further point of criticism is that a considerable amount of medical care rendered under present conditions is mechanical. Patients reporting to the outpatient departments of some teaching hospitals are not uniformly treated with consideration and respect, although given all possible laboratory tests and x-ray examinations. In the New York plan, we found more physicians possessed of technical competence than those also equipped to deal with their patients as people. It seems likely that this has a bearing on the failure of the public to seek preventive services and to maintain consistent medical relations.

Anything done in the future should certainly be designed to avoid sterile mechanization. Rather, the conditions under which medical service is rendered should provide incentive for the development of the personal relation between physician and patient. If this could be accomplished, there is no doubt that more emphasis would be placed on the education — in contradistinction to the training — of those entering medicine and that psychology and psychiatry would receive more attention both in the curriculum and in research than they are now accorded.

The second requirement placed on reform must be in the interest of the physical sciences. This is given second place because scientific development is in large part a function of broader forces than medicine controls. It ebbs and flows with basic social and economic conditions, and so long as America remains economically strong and socially dynamic, great energy and large resources will be channeled into basic scientific research. But the system of medical distribution should contribute to the multitude of undertakings required either to adapt the products of pure research to medical use or to investigate the nature and causes of disease. At present, only from the distribution of drugs and medicines is there a financial contribution to research that stems directly from the users. Otherwise, the distributive system does not automatically produce the sinews of development. For the rest, medical research is dependent on the charity of individual physicians donating time, of philanthropists providing endowments and of foundations making grants. A small amount, which may soon be larger if current efforts in Washington succeed, comes from government. Clearly, it is not inherent in the nature of medicine to depend on benefactions for so vital a part of its work. It is merely that society has not yet caught up with the change that has taken place since the principal source of medical care was the church. No one suggests that voluntary contributions to the cause of medicine should not be welcomed, it is only that the degree

of dependence on charity is no longer appropriate to the task.

It should be added that since the public is now orientated toward medicine, an additional charge labeled "for scientific research" on bills for professional or hospital services would probably meet with less resistance than an equal charge for personal preventive services.

The financing of hospitals has more nearly kept pace with their evolution than has that of research. Here, a change of functions since the days when hospitals were pesthouses and hostels is obvious. As prime requisites in both the production and the distribution of medical care, the distributive system should effect adequate means of support. To make up present deficiencies in certain parts of the country, the expedient of federal aid as embodied in the Hill-Burton Act, recently adopted by Congress, seems desirable, but it would surely be functionally and organically sounder to place hospital financing directly into the total medical scheme. We are well on the way to doing that, the deficits of our voluntary hospitals in New York are down to less than 10 per cent of operating costs.

Obviously, a reformed system of distribution should contribute more than money to the development of medical research. It should be so constructed that physicians and others with a bent for investigation are given an opportunity to participate in systematic research without having to establish themselves in a metropolitan center. Smaller communities need that caliber of professional ability and interest. The mechanical difficulties involved are obvious and great, but the concept of central hospitals with satellite institutions and staffs is already current and attempts to apply it have been started.

* * *

The final criteria of an adequate distributive system for medicine are both economic. In the first place, the personnel and facilities should be organized for maximal efficiency, and secondly, the cost of producing and distributing medical care should be equitably apportioned.

The word "efficiency" carries a connotation of regimentation and mechanization that it ill deserves. That is efficient which most directly accomplishes the purpose. The purpose under consideration is to provide a complex personal service, whose main elements I have attempted to define. Thus, it would not be efficient medicine for this hospital to employ ten doctors from nine to five for five days a week to give physical examinations and only physical examinations. By the same token, it is not efficient medicine — no matter how great the apparent saving in dollars — to rotate clinic staffs in such a way that each time a patient visits the clinic he is seen by a different physician.

treated conditions and what happens when the barrier of fees is removed

One feature of the plan was a preadmission medical examination conducted by general practitioners selected from the panel by the applicant, and it should be noted that the Medical Board found a great variation in the quality of the examinations. According to the reports submitted, conditions requiring medical attention were found in 30 per cent of the applicants, and the nature of the conditions suggested that fully a third of these had not received such attention. When it is considered that the majority of the subscribers were acutely conscious of their health or at least more aware of medical care than the average person, as indicated by the fact that they had joined the plan, it is evident that a substantially higher proportion of the population at large are avoiding medical attention.

After admission to the plan, the subscribers averaged about six yearly calls on a general practitioner—that is, the participating physicians had six hundred calls per hundred subscribers, of which five hundred and fifty were in the office and fifty at home. It has been reliably estimated that this over-all figure represents about double the number of services used under postpayment. The participating physicians who had the largest practices reported only a negligible amount of hypochondria or abuse of privilege among the subscribers, the overwhelming majority of calls were for illness, organic or functional, that needed medical attention. Although many of the conditions were not important, others were, and the uninformed patient had no way of distinguishing one from the other except through pain.

The second, and more surprising, fact disclosed is that interest in and concern for the maintenance of the patient's health is the exception, not the rule, among general practitioners. The reason is not far to seek: there is little effective demand for personal preventive medicine. Whatever the practitioner may have learned at medical school and the hospital, the services for which patients seek care and pay determine the direction of his interest. The treatment of acute upper respiratory infections, gastrointestinal disorders and children's diseases, the reduction of fractures and dislocations and attendance on obstetric cases comprise the average general physician's practice. Thorough physical examinations and, except for hypochondriac patients, consultation on general conditions of health are not sought.

Also impressive was the contrast between the co-ordination of care effected by practitioners affiliated with leading hospitals when their patients needed specialist attention and the lack of co-ordination in similar cases when handled by practitioners without good hospital connections. Numerically, almost a quarter of the subscribers were judged by the general physicians to require some type of specialist

service in the course of a year. It is believed that closer association between practitioners and specialists, such as that created by group practice, would raise this proportion, high though it already seems in comparison with the 15 per cent often cited.

Finally, the most striking phenomenon observed is the degree of ignorance shown by people in all walks of life concerning both what medicine has to offer and how to go about obtaining medical attention. Only about a third of the people in New York have a family physician, according to a survey made several years ago. Whereas this proportion is doubtless lower than would be found elsewhere, there is little doubt that the institution of the family doctor has declined sharply the country over during the past quarter century, and nothing has taken its place. The result is that an ever-increasing number of people are medically adrift. In the classic sense of the term, they might be called the "medical proletariat." To these people, physicians are to be called, like the fire department, in emergencies only. And when the emergency arises, they find that they do not know whom to call. There is evidence of a growing reliance on hospitals as sources of medical referral, but the testimony of a relative or friend, the corner druggist or merely the shingle by the door is usually decisive.

Still another sign of dislocation is the drift of these unattached patients to specialists, or to those whom they believe to be specialists. Everyone who is not a physician has great faith in his ability to diagnose his own ailments, and the patient with a backache is taken to "Mrs. Smith's wonderful bone specialist." An internist of my acquaintance wryly remarked that in a surprising number of these self-referred cases, the patient's diagnosis is confirmed.

* * *

This review of deficiencies in the distribution of medical care, fragmentary and impressionistic though it is, may seem an effort to frame an indictment. It is not; the purpose is rather to delineate a problem. American medicine as a social institution is out of balance: the medical arts and sciences are capable of far more than the distributive system delivers. And in one broad and important field—namely, the conservation of personal health—the limitations of distribution are reducing technology to a state of virtual atrophy.

The question now facing us is how, precisely, to reform the system of distribution to provide better, as well as more, medical care. Certainly, the answer is not a simple one. Anyone who has been closely associated with medical care must realize that much that is actually and potentially best in medicine is volatile. For all that the physical sciences have contributed to diagnosis and treatment, a large part of the physician's technic is the product of art rather than of laboratory science. The physician retains many of the attributes of the priesthood.

staffs of men and women working in the community, observing medical conditions with painstaking care, consulting the experience of representative people, examining the results of local medical plans and interpreting their findings as scientists will produce sound answers to the fundamental questions at issue.

The problem of social medicine is now acute, but so long as American society remains dynamic, the

problem will also be chronic. Changes in general society and within medicine itself will call for constant adjustment of the distribution and technology of medical care to maintain a balance. Only consistent, scientific examination of the people's health and evaluation of the findings in the light of broad social understanding will achieve the flowering of medicine that now lies in the wood.

THE TEACHING HOSPITAL'S SERVICE TO THE PUBLIC*

ALLAN M. BUTLER, M.D.†

BOSTON

THAT ether was introduced into the practice of medicine in a hospital such as the Massachusetts General Hospital was not an odd chance. Such a large teaching general hospital provides the various factors essential to the intelligent introduction of new therapeutic agents and technics to medical practice. Indeed, the actual application of all new medical knowledge must almost always be accomplished through such a hospital. Where else can be found an adequate number of patients under the close and continuous observation of competent physicians who have the appropriate training, the curiosity, the time and the support of adequate laboratory facilities and personnel? The fact that such therapeutic agents as x-rays, radium, the sulfonamides, penicillin, streptomycin and the radioactive isotopes were introduced into medicine through teaching hospitals demonstrates their particular suitability for determining the methods by which the contributions of science may be applied to the care of patients. Moreover, the clinical investigator is often the first to see the clinical application of scientific knowledge. Although his role usually falls under the category of applied science, his contact with both clinical medicine and scientific thought and technic gives him interests and opportunities that the basic scientist may not have. The experimental contributions of the clinical investigator, therefore, may open fields that basic science and industry may cultivate with great profit.

The discovery of the anesthetic value of ether by Long, a physician, and Morton, a dentist, that is commemorated today opened a field of scientific investigation to chemists and physiologists that was effectively cultivated by industry to the great benefit of society. Banting, an orthopedic surgeon, and Best, a medical student, discovered insulin. Clinical investigators in hospitals such as this perfected the application of this new therapeutic agent

to clinical medicine, chemists produced the crystalline substance and developed other compounds, industry made them available by mass production, and millions of patients with diabetes and other equally serious ailments benefited. Drs. Minot and Murphy, both clinicians in the teaching hospitals of Boston, by discovering the effectiveness of liver in the treatment of pernicious anemia similarly contributed not only a specific therapy for a human ailment that had previously been fatal but also ideas that stimulated scientific work and provided opportunities for pharmaceutical endeavor that have been pursued efficiently. Fleming, working on the bacteriocidal property of tears, and Waksman, a soil bacteriologist, discovered, respectively, penicillin and streptomycin — therapeutic agents that have revolutionized medicine by reducing morbidity and mortality and that have resulted in expanding industrial activity and earnings. What does it matter whether these contributions are basic, biologic or applied science? For science is no end in itself. Their significance is that they are contributing to human health, wealth and happiness. Can the same be said of atomic energy, the latest contribution of basic science?

An extreme and puzzling example of the unique position of the clinical investigator and the teaching hospital arises in a consideration of how investigation of the prevention and treatment of mental disease will be advanced. Are we to rely on the basic sciences to break through the impasses that now confront us in this most distressing and costly field of medicine? Or should we support the clinical investigator, whose approach to the subject appears so unscientific to the scientist? I shall not attempt an answer, but shall venture the guess that the contributions that will ultimately open this field to scientific exploration will come from clinical investigators working with patients in teaching hospitals, not from basic scientists working in laboratories with mice or test tubes, or from the psychiatrists of overcrowded and underfinanced mental hospitals. The opportunities offered by the patients,

*Presented at a symposium "The Hospital in the Community" held during the Ether Day Centenary of the Massachusetts General Hospital, Boston, October 16, 1946.

†Professor of pediatrics, Harvard Medical School; chief, Children's Medical Service, Massachusetts General Hospital.

But to the extent that professional time and expense and the time of the patient can be saved without sacrificing necessary thoroughness and the personal relation, efficiency is gained. Medical group practice seems able to attain that end. Coordination of the patient's care is facilitated by staff organization, specialized facilities and unit case records. Hours of patient time and at least quarter-hours of doctor time are saved when special procedures or consultations are required. If these savings applied to only 15 per cent of cases, they would be important, but as noted above, the experience in New York suggests that a substantially higher proportion need the attention of a specialist. In addition, group practice reduces the expenses of the individual physician, practitioner and specialist alike, because facilities and ancillary personnel are shared. With everything taken into account, it is not an exaggeration to say that group practice can increase the efficiency of delivering medical services by 50 per cent.

Of course, no institution is better than the people who serve it, and medical-practice groups follow the rule. They do not guarantee a high standard of medicine, all they offer is a device to make good medicine easier to produce and cheaper to deliver. As such, they are key points in the reform of medical distribution.

The final requirement placed on reform is that it shall equitably apportion costs over the population. Health insurance is one method—voluntary or compulsory, or both. Direct taxation to raise the needed funds in whole or in part is still another method. But before any money is raised or insurance premiums are paid, the public should know precisely what is to be paid for and how the quoted cost was arrived at.

For example, a system of insurance that applied the methods and fees of the New York Workmen's Compensation Act to medical care for the population as a whole would raise the national health bill from four or four and a half billion to something over ten billion dollars. If, on the other hand, group practice were prevalent so that fixed-rate payments could be made to medical groups, the same quantity of service would cost only about seven billion dollars (I say "only" advisedly—the amount would still be less than that spent on automobiles).

It must immediately be said that these estimates cannot pretend to be precise, for experience with prepayment in this country is limited. At most, 10 per cent of medical costs are now paid through insurance, and the great bulk of that goes for hospitalization. Regarding professional services, experience is fragmentary and diverse—indicative but in no way conclusive.

In view of the paucity of experience, particularly the widespread ignorance of what medicine can and should be, the proposal to set up an all-inclusive, federal system of paying for medical care

seems premature. Although we may know enough to take the first strokes, it does not seem judicious to leap off the dock.

Nevertheless, it must be recognized that a large number of people in the United States cannot afford to pay, by themselves, for even the most efficiently delivered medical care. Whole areas now suffering from medical impoverishment cannot possibly support an adequate standard out of their own resources. It is unreasonable to suppose that these deficiencies can be made up without bringing the tax power into play. Medical care is surely an appropriate object of community expense, not only as a means of relieving suffering but also, even more, as a measure for raising the general capacities of the people. If properly expended, public monies disbursed for health services constitute an investment.

The art is to spend the funds properly. That we must learn, as we learn any art, by doing and closely observing the results. "*Far una prova*," the Italians call it—"to make a proof," rather than to wait for proof to arrive. Active experimentation at the local level is what is needed most.

It is pleasant to be able to report that New York is at work. The most notable attempt in this country to put into practice, on a community-wide scale, the concepts of medicine implied in this paper is the Health Insurance Plan of Greater New York, which, after more than two years of arduous preparation, should be in operation by the new year. But many similar attempts are needed throughout the Nation, and they should not be delayed. Only local knowledge gained by experience, as well as local understanding of what medicine is and can be, will ensure the delivery of good medicine in the future.

* * *

The restoration of medicine as a social institution to a state of equilibrium within itself is a job crying for the participation of the most highly qualified physicians. Thus far, leaders in the profession of medicine have taken an active part in only a few communities, leaders in the business of medicine have taken rather too great a part. Why is this not a subject for the medical schools? It is as much a matter of concern to medicine as foreign policy is to government. Statesmanship is needed, and where else should one look than to the medical schools?

What is required is the creation of a new discipline within medicine—it might properly be called "social medicine," which would concern itself with the relation of the medical arts and sciences to society. It is not a subject to be handled as an extracurricular activity at occasional institutes and conferences, it demands the same kind of concentrated attention and expertise as any major field of investigation and practice. Training in medical administration will not answer, useful though administrators would be, for something worth administering is necessary. Nothing less than organized

Scientific Research and Development — studies that systematically defined the efficient use, in the control and cure of malaria, of both the heretofore empirically used agents and the new and superior synthetic antimalarial drugs developed under this effectively planned and executed research program.

The experience obtained during these studies demonstrated again that the optimal utilization of medication in man can be defined only through clinical testing. The behavior of these drugs in the human being could not be predicted reliably from studies on animals other than the monkey. The same reservation is true of operating procedures. These studies also demonstrated the limitation even of the monkey owing to the difference between its susceptibility to disease and man's and to the difficulty of producing in the monkey the conditions simulating those demanding operative therapy in man. This does not mean that patients are used as guinea pigs. It means that teaching hospitals can give patients newer and more effective therapy than can be obtained elsewhere. Incidentally, it does not mean that as much information as possible should not be obtained on mice, rats, chicks, ducks, guinea pigs and other animals before studies are undertaken with the monkey. Only in that manner will the difficult and expensive monkey experiments be efficiently conducted, and will all the information be obtained that makes utilization of new drugs and operative procedure in man safe.

In this connection it may be remarked that the antivivisectionist is one of the few people who eat their cake and have it too. So long as he is unsuccessful in prohibiting such clinical investigation, he may safely indulge in denouncing that by which he happily benefits. For no doctor will give him a drug or subject him to an operation that has not been tried and perfected by experimentation.

Such development of new and better therapy is expensive. The O S R D studies on malaria therapy for two and a half years cost the Government some \$5,500,000. The clinical testing conducted by this hospital, which was one of five clinical testing units under the program, cost \$220,000. The total cost of the clinical testing probably approximated \$1,500,000. Yet had the war in the East lasted another year the reduction in the drug bill alone from the use of the new compounds instead of quinine and quinacrine would have paid for the studies. As it is, this saving will be realized by society in general, and a substantial profit will accrue to at least one pharmaceutical company.

The opportunity of similarly improving and developing therapy in other fields is wide open.

The field can best be cultivated not by collective farming but by the group services of teaching hospitals.

The effective utilization of these group services can be increased in other ways. For example, a paying patient rarely obtains the medical care that these group services are particularly qualified to give unless he is admitted to a hospital and occupies a hospital bed. Frequently this is unnecessarily confining and expensive and may deprive some other patient of the bed he really needs. The Mayo Clinic is, I believe, one of the few group practices that is equipped to make its hospital staff and laboratory facilities available to ambulatory patients.

One other consideration deserves mention because it may affect the future of the group services of teaching hospitals that — I hope we all agree — are fundamental to the improvement of medical care. If the current extension of medical, as differentiated from hospital, insurance is successful enough under either private or legislative plans to prevent illness itself from resulting in medical indigence, the services of the highly trained and integrated group practices of teaching hospitals may be curtailed. The patient who has heretofore come to the wards of such hospitals may for better or for worse elect to be cared for by an individual physician in either a teaching or a nonteaching hospital. The problem that this presents is not dependent on the extension of governmental insurance. As a matter of fact, the legislative proposals, except so far as they may be more successful in covering more people, present less threat in this respect than the voluntary schemes. They permit the patient free choice of a physician, groups of physicians or hospitals, whereas the voluntary schemes provide for free choice only of a physician. The legislative proposals also make provision for financing medical teaching and research. The voluntary plans do not.

Such a possible effect of extension of medical insurance does not indicate, I trust, that indigence must be perpetuated in the interest of improving medical care. It does mean, however, that, if the group services of teaching hospitals are to weather the critical years ahead, they must be strengthened by increasing the public's understanding and appreciation of the services they render. It means that we must, in a business-like manner, assure payment for the benefits society receives. Let us consider the means of doing these things without prejudice and in the light of what is best for the public as a whole solve the problems and take advantage of the opportunities to develop the teaching general hospital to its full potentialities.

staff and research facilities of this hospital, with its department of psychiatry in intimate association with every division of this general hospital and with the McLean Hospital, were thoughtfully conceived and are being well pursued. But the personnel of both that department and the McLean Hospital are inadequate — inadequate in terms of diversity of training, number and especially time free of the overwhelming demand for the meager therapy that is available today.

A teaching hospital not only provides the facilities essential to clinical investigation but also develops groups of investigators that are larger and more enduring in life, though not in memory, than the individual. These groups, led by the Churchills, Meanses, Cobbs, Aubs, Bauers, Albrights, Whites and others, are continually working for all of us and our children not only by their contributions to new and better medicine but also by educating you and all physicians and by caring for patients. They largely provide the stock in trade of medical care that your good doctors sell you. They teach the medical student, the intern, the resident, the graduate fellow and the postgraduate physician. They give the lectures at medical-society meetings and write the articles in medical journals. They determine the quality and the nature of the medicine of tomorrow. In doing this they are the best salesmen of pharmaceutical products. And while doing this they are personally giving all of us, day and night, the special care that they, through this institution, are particularly equipped to give.

What is the public's and industry's and your appraisal of the worth of such service? Compare the salaries and equipment of hospitals with those of industry serving society by developments pertaining to automobiles, airplanes, agricultural implements, radios, rubber, plastics and chemotherapeutic agents. Salaries of \$2,000 to \$4,500 are usually paid clinical investigators. The provision of more is difficult. Moreover, appointment is usually on a short-term basis, and too frequently a salary is dependent on a year's grant whose renewal may not be determined until two weeks before its expiration date. There are several men in this room whose contributions to medical knowledge have made them known in every country in the world that enjoys the benefit of modern medical science. They get just such salaries. The technical workers in clinical laboratories — college graduates and highly skilled persons — fare no better, receiving salaries of from \$1,500 to \$2,000 as compared with the \$2,000 to \$3,000 available to them in industry. Yet clinical research depends in no little degree on the quality of their work. And the quality of medical care depends more and more on the information that such technicians give physicians or surgeons concerning the composition of the blood, its type, the micro-organism that is involved or the tumor that is or is not malignant.

One wonders if the pharmaceutical companies are wise in putting more money into advertising than into the hospitals that introduce their products and educate doctors in their use.

Is it because the charity tradition still pervades the public's concept of the large teaching urban hospital that the public, in making payments under hospital and medical-insurance plans, does not pay costs and thus still leaves much to charity? Does that tradition, as well as the educational character of these hospitals, encourage sentimental support rather than a realistic and material purchase of the concrete services rendered? We speak of supporting hospitals but not of supporting industries. Each of us buys what he gets. Perhaps the inadequate support of hospitals reflects the thought that medicine is concerned with lessening illness rather than producing health — the value of the institution, therefore, being conceived of in negative rather than positive terms. Yet people spend literally billions on doctors and pills. Medicine is, I believe, the third largest business in terms of money spent. But the teaching hospital, which determines in no small way the quality and improvement in medical care, is faced with possible bankruptcy. A past president of the American Hospital Association, who knows hospitals, remarked at a meeting a few months ago that there were probably only a dozen hospitals in the United States that would avoid insolvency in the next few years unless there is a drastic change in hospital financing. If the public does not finance the difference in the cost of medical care given by such institutions as this and that given by the smaller hospital, how can the teaching hospital continue to provide the difficult medical care for which doctors refer patients to obtain the treatment that is not available elsewhere? It is that type of care that makes the value of this institution, both to the patients who come here and to all those who never come here but who benefit by the doctors, nurses, social workers, dietitians and technicians who are educated here. It is the new, the carefully controlled and the well defined therapy that such hospitals as this provide that makes them of value to industry.

They could be made of far more value. The most effective utilization of a therapeutic agent demands at least a knowledge of its absorption and distribution within the body, of its excretion and degradation and of its toxicity and therapeutic effectiveness in relation to concentration in body fluids and tissues. This information has been obtained for only a few of all the many therapeutic compounds used today. One may well ask if we are administering such generally used substances as the barbiturates, hydantoins and digitalis preparations to no better advantage than we used quinine and quinacrine prior to the recent studies conducted under the direction of the Board for Co-ordination of Malaria Studies of the Office of

pressed the bulk of the cut surface was frankly red and of a distinctly soft consistence. Close scrutiny of these areas revealed a completely collapsed and considerably disintegrated architecture of the liver lobules. The entire gross picture, therefore, was interpreted as showing a marked degree of acute atrophy of the liver in what might be termed a predominantly "red" rather than a "yellow" state.

The histologic picture, as revealed in several different sections, showed extensive liver damage of a decidedly acute nature (Fig. 2). There were marked necrosis and destruction of the liver-cord cells and, over large areas, complete collapse

The gall bladder was of normal size and thin walled and contained no calculi. Its fundus protruded almost 4 cm. beyond the upper edge of the markedly atrophic liver. The extrahepatic biliary passages were collapsed and contained only a slight amount of thin yellow bile.

The spleen was of average size, weighing 160 gm., and was grossly not remarkable. Microscopically there was marked atrophy of the malpighian follicles. There was also considerable congestion of the red pulp with dilatation of the sinusoids, which contained moderate numbers of leuko-

of the normal architecture. In these collapsed areas the lobular pattern had entirely vanished, there remained only scattered regressive liver cells singly and in disjointed groups within the condensed and inflamed stroma (Fig. 3). Many of the necrotic and necrobiotic liver cells contained a great deal of fine, granular, golden pigment, apparently bilirubin or lipofuscin. In addition, there was distinct proliferation of the bile ducts, as well as considerable swelling of fixed tissue cells. Numerous lipid-laden histiocytes were found, and there was much acute inflammatory infiltration, particularly in the periportal areas. Many bile canaliculi and a few smaller bile ducts were distended with bile thrombi. Other small bile ducts contained neutrophilic exudate within their lumens. In the more severely damaged areas there remained only small isolated groups of apparently undamaged liver

cytes and plasma cells, in addition to erythrocytes. The reticulum was slightly increased.

The kidneys were of average size, with thin, easily removable capsules. Aside from minimal persistence of embryonal lobulation they presented only slight diffuse, fine granular

cords. Finally, the preserved areas described grossly revealed fair-sized, intact remnants of liver parenchyma. Here, there was considerable edema of the intervening sinusoids, which were exceedingly dilated and filled with granular detritus. The liver cells, although intact, showed distinct regressive changes, with vacuolization and granularity of the cytoplasm. Here, too, were occasional necrobiotic and necrotic parenchymatous cells, whereas the bile canaliculi showed numerous bile thrombi. The over-all histologic picture was that of a severe degree of acute toxic necrosis, such as that seen in acute yellow atrophy.

FIGURE 2 Photomicrograph of the Liver

scarring of the cortices. On section the parenchyma revealed distinct icterus, a regular corticomedullary junction and a cortex of about 7 mm in thickness. The major renal vessels, the pelves and the ureters were not remarkable. The urinary bladder was completely contracted and contained only a few drops of urine.

Microscopical sections of the kidneys revealed interesting findings. Aside from a rare hyalinized glomerulus, the renal corpuscles were entirely intact. Occasionally, the glomerular spaces were slightly dilated and contained droplets of deep-pink-staining material.

The tubular system, however, showed severe alterations

ACUTE YELLOW ATROPHY FOLLOWING CINCHOPHEN ADMINISTRATION*

Report of a Case

ALFRED R. LENZNER, M.D.,† L. MAXWELL LOCKIE, M.D.,‡ AND CHARLES F. BECKER, M.D.§

BUFFALO, NEW YORK

ABOUT twenty years ago Cabot¹ first reported a case of acute yellow atrophy allegedly due to cinchophen. Although similar cases have been recognized since that time, clinicians who use cinchophen with no observed untoward effects have minimized it as a hepatotoxic agent. One series has been reported, for example, in which cinchophen was given to 2500 patients without a fatal case.²

The toxic manifestations of cinchophen against which the physician is usually cautioned are chiefly those of the skin. Among them, urticaria and the erythematous morbilliform rashes are said to be most frequently encountered. But perhaps more important are signs indicative of hepatic damage. These include nausea, emesis, dark urine, icterus and discomfort in the right upper quadrant. With these symptoms the dermatologic complaint is, unfortunately, an infrequent one.

The following case of acute yellow atrophy terminated fatally twelve days after the ingestion of 2 gm of cinchophen.

A 59-year-old Jewish housewife was admitted to the surgical service of Dr. Herbert A. Smith with the chief complaints of painless progressive jaundice, anorexia and nausea of 6 days' duration. The first symptoms had been extreme anorexia and nausea, without emesis or abdominal discomfort. These were accompanied by jaundice and dark urine, both of which had deepened rapidly. Two days after the onset of these initial symptoms, an attempted gall-bladder visualization had failed. Fluoroscopy with roentgenograms had disclosed no abnormalities of the esophagus, stomach, duodenum or abdomen. Continued nausea had prevented food intake of any consequence almost from the onset. Listlessness had progressed to drowsiness, and fleeting episodes of disorientation had become evident on the day preceding admission.

The patient had seen a physician for a long-standing arthritis of the ankles. She had taken a total of 2 gm of cinchophen on the day preceding the onset of the initial symptoms. So far as could be determined from her physicians and family, cinchophen had not been given previously.

The past history revealed that during the preceding 4 years the patient had been receiving salicylates and injections of vaccine, as well as physiotherapy for the ankles. These measures had been instituted by several physicians for rheumatoid arthritis. She had always been ambulatory. Since for 1 year before admission she had experienced mild postprandial eructations and because of obesity, fatty foods had been eliminated from the diet. The eructations had been relieved, and the weight remained constant. There had been no change in bowel habits. Twenty-three years previously, vaginal hysterectomy had been performed under ether anesthesia for a fibroid uterus. There was no history of previous icterus or of transfusions.

Physical examination at the time of admission disclosed a moderately obese, somewhat disoriented woman with a deeply bronzed icterus. The pupils were regular, equal and normally reactive, neurologic survey revealed no abnormalities. There were no tophi. The tongue was somewhat dry, and the mucous membranes icteric. The heart and lungs were not remarkable. Neither the liver nor the spleen was palpable or tender. Rectal examination was negative. Rheumatoid arthritis of the ankles was present. The blood pressure was 150/80, the temperature, pulse and respirations were normal.

The results of certain laboratory procedures are presented in Table 1. The serum alkaline phosphatase was 7.3 Bodansky units per 100 cc. A cephalin flocculation test was + + + +, and the prothrombin time, 30 seconds (normal, 16 seconds). Urinalysis revealed a few red and white cells, a positive test for bile in a dilution of 1:100 and a specific gravity of 1.014; there was no albumin on admission, but a + test was obtained on the following day. The stool was tan gray. The blood film showed a uniformly, mildly macrocytic picture. Examination of the blood revealed a red-cell count of 4,500,000, with 13.5 gm of hemoglobin (photometric—normal, 14.4 gm). The hematocrit reading was 49 on the same sample of blood. The mean corpuscular volume of the erythrocytes, therefore, was 109 cubic microns. The white-cell count was 7000 on admission, and 17,000 on the fourth hospital day, 70 per cent of the leukocytes were neutrophils.

The course was rapidly downhill. Drowsiness and disorientation progressed to semicomatose by the 2nd hospital day. Severe, irreversible hepatic damage was present, as evidenced by the cholemic state and by a definite decrease in the size of the liver to percussion on successive examinations. The plasma prothrombin time remained elevated to 30 seconds even after the administration of menadione bisulfite. No ecchymoses were observed at any time.

It was decided to give a massive dose of methionine intravenously. Accordingly, 15 gm of crystalline *D,L* methionine (0.25 gm per kilogram of body weight) was dissolved by boiling in 500 cc of a 10 per cent solution of casein hydrolysate. This was infused without reaction over a period of 4 hours. The natural course of the disease progressed unaltered, however. Despite adequate parenteral fluids, oliguria was noted on the following day. Coma deepened, and the atmosphere in the patient's room soon became permeated with a peculiar, musty odor, not unlike that of the infused methionine solution. Signs of free peritoneal fluid developed, in addition to those of bronchopneumonia, and the patient died on the 4th hospital day—12 days after the jaundice and dark urine had first been noticed.

Autopsy. The body was that of a moderately proportioned woman measuring 147 cm in length. The integument and conjunctivae exhibited deep icterus. There was no peripheral edema. Exposure of the peritoneal cavity revealed 1500 cc of brown-yellow ascitic fluid. An unusually atrophic liver (Fig. 1) lay considerably recessed beneath the right costal margin. Its surface was irregular, with low, plateau-like, tawny-brown elevations separated by rather extensive, irregularly shaped, depressed deep-red areas. The organ weighed 650 gm (normal weight, 1200 to 1400 gm).

The cut surface of the liver presented a striking picture. Only a few portions of the parenchyma remained intact. The largest sections, which were situated chiefly in the superior portion of the right lobe beneath the capsule and also in the caudate lobe, varied in size from that of a large cherry to that of a walnut. In the left lobe there were a few much smaller remnants varying from match-head to pea size. All these remnants were grossly green yellow, suggesting icterus and considerable fatty change. There were no structures that could be interpreted grossly as nodular regenerates. The intervening tissue, which com-

all of which autopsy was performed, — noted in every case that there was evidence of a "hepatitis" or of a "degeneration" of the parenchyma of the liver. Each of his own cases exhibited a toxic cirrhosis after a terminal hepatic illness of several weeks' duration.

It is of interest to compare certain of the histologic findings in the case presented above with those observed by Lucké⁴ in his study of fatal epidemic hepatitis. In our case, in which there was no appreciable zonal pattern of destruction in the liver lobule, such as that described in epidemic hepatitis, the agent apparently attacked all regions within the lobule with equal severity, producing all stages of cellular disintegration — fatty changes, vacuolization and coagulation of cytoplasm — and cellular death. This pattern of necrobiosis and necrosis, in itself, also differs from that observed in fatal epidemic hepatitis, in which rapidity and completeness of cell destruction are distinguishing features.⁴ In the regions still intact, however, the inflammatory infiltration was more marked in the periportal areas, consisting largely of neutrophils.

We observed no endophlebitis of the central veins. Nor was there any recognizable persistence of the outline, by small proliferating bile ducts, of the completely destroyed lobules. Both features were described in epidemic hepatitis. A characteristic of acute yellow atrophy that was well shown in this case was the extraordinarily rapid disappearance of many of the damaged liver cells. Lucké, also noting this phenomenon in his material, assumed that the necrotic cells had been swept away by enzymatic action. The tempo of the disease in our patient was apparently of such rapidity as to preclude the development of nodular regenerates.

Recently, studies on acute or fulminant epidemic hepatitis running a fatal course in ten days or less have appeared.^{5,6} In most cases the liver presented a moderate reduction in size, with a smooth or occasionally finely wrinkled surface. Nodular regeneration, prominent in the subacute form of this disease, was absent or minimal. Microscopically, extensive destruction of liver cells dominated, usually involving uniformly all parts of the liver. Apparently, this occurred initially in the central zones of the lobule. Even in cases with a clinical history of brief duration, cell destruction was often far advanced, and complete lobules had been swept away. Inflammatory reaction, most conspicuous at the lobular periphery, was severer than that in the subacute form of the disease.

The case presented above, however, differs in certain respects from fulminant epidemic hepatitis, notably in the size and shape of the liver, the gross appearance of the cut surface and certain microscopical findings, such as the presence of stages of cellular degeneration and the absence of zonal patterns of disintegration.

So far as the cause of the hepatic damage is concerned, can the administration of cinchophen be considered merely an unfortunate coincidence? The report by Palmer and Woodall⁷ of 88 deaths in 191 recorded cases of hepatitis associated with cinchophen seems sufficient clinical proof for the hepatotoxic potentialities of this drug in the susceptible patient. MacBryde⁸ states that a number of cases of toxic hepatitis consequent to cinchophen undoubtedly have been mislabeled acute infectious hepatitis. Frequently, as in the case presented above, a history of cinchophen ingestion is not elicited at the initial inquiry.

It has been observed that cholemic nephrosis has received much less attention than the condition merits.⁴ Fahr⁹ described the findings in cholemic nephrosis in some detail in 1925. Ayer's¹⁰ pathological analysis of renal lesions in 18 infants who were jaundiced from congenital biliary atresia is perhaps more comprehensive than any written about this lesion. He consistently found pigmented bile casts in the distal convoluted and collecting tubules in his cases.

In a subsequent study of post-transfusion uremia, Ayer and Gauld¹¹ concluded that the essential features of the renal lesions following fatal transfusion reactions were similar to those seen in the kidneys of infants with biliary atresia. The findings in the kidneys of patients succumbing to subacute epidemic hepatitis also correspond to those described by Ayer.

The tubular lesions seen in our patient also closely paralleled those reported by Ayer in jaundiced infants. Not heretofore described, however, in the nephroses accompanying acute yellow atrophy, acute or subacute epidemic hepatitis, obstructive jaundice or post-transfusion uremia is the presence of a considerable amount of calcium in the cortical collecting tubules and their peripheral branchings and also within occasional distal convolutions. Flocks¹² recently reported asymptomatic pelvic and intrarenal calcium urolithiasis in its early stages. Although its exact intrarenal location is not described, — except within the tubules, — it is presumably located within the collecting tubules and ducts of Bellini in the pyramids. Flocks termed the substance a "phosphate."

What is the mechanism of this calcium precipitation? Several possible causes can be excluded. So far as we were able to determine, the patient had never taken irradiated ergosterol. Except for short periods she had been ambulatory, hypercalcaemia due to osteoporosis from immobilization being thus eliminated. At autopsy the parathyroid glands were not conspicuous, nor were there any evidences of multiple myeloma. Urinary stasis, infection and heavy metal intoxication were also absent.

It seems then, that few possibilities remain. So far as we know, the infused methionine solution did not contain significant amounts of calcium salts.

The proximal parts of the collecting ducts exhibited marked albuminous degeneration with a great deal of concentric debris and droplets of eosinophilic material within the lumen.

FIGURE 2. Photomicrograph of the Liver.

It is a cross-section of a collecting duct of the liver showing eosinophilic material within the lumen.

Most of the thin segments were dilated and empty, but a few contained eosinophilic casts. The ascending limbs of Henle's loops occasionally contained similar casts and

appeared. Occasionally, cystic structures were seen—probably dilated convolutions of collecting ducts—lined by flattened epithelium. These contained a similar eosinophilic granular substance.

Perhaps most interesting were the lesions in the collecting tubules. The peripheral portions of the collecting ducts showed rather ordinary dilated lumens with numerous flat cells. Many of the collecting tubules in the connective portions of the medullary rays contained considerable amounts of a peculiar amorphous granular material similar to the noted in the duct convolutions. This substance, taking a dark bluish-gray color in a hematoxylin-eosin preparation, gave a positive reaction with the von Jaksch stain for cholesterin (Fig. 3). With this reaction it was apparent that although the bulk of this material lay within the lumen, small amounts were deposited in the cytoplasm of the tubular epithelium as well.

The small capillary vessels of the stroma showed minor hyperemia, especially in the pyramids. The small arteries revealed moderate elastic thickening.

Both lower lobes of the lungs grossly showed diffuse alveolar emphysema with slight to moderate hyperemia in

FIGURE 3. Photomicrograph of a Kidney.

The section shows a dilated collecting duct of the kidney with eosinophilic material within the lumen.

hemorrhage, some of the alveolar parenchyma. Histologic sections showed marked signs of recent pneumonia.

The heart was of normal size and grossly revealed entirely normal chambers, valves and coronary arteries. Histologically, the myocardium showed only slight interstitial edema with scattered plasma cells and leukocytes, and distinct edema swelling of the myocardial bundles.

All other organs, including the pancreas and the thyroid, parathyroid and adrenal glands, were normal. Permission was not granted for examination of the brain.

The findings in the liver in this case correspond well with the classic pathological picture of an acute toxic necrosis. That the disease was of a fulminating character clinically is amply shown pathologically by the severity of parenchymatous damage, the acute inflammatory response and the absence of regeneration or of reactive fibrosis. Reichle,³ in a review of 7 reported cases of death due to cinchonism, to which he added 2 cases of his own—in

many a bile collector. Bile casts which were more frequent in the ductal convolutions, were rarely associated with 1 or 2 mononuclear cells within the lumen (Fig. 4). In several distal convoluted tubules a dark-blue granular substance

The case presented above, however, differs in certain respects from fulminant epidemic hepatitis, notably in the size and shape of the liver, the gross appearance of the cut surface and certain microscopical findings, such as the presence of stages of cellular degeneration and the absence of zonal patterns of disintegration.

So far as the cause of the hepatic damage is concerned, can the administration of cinchophen be considered merely an unfortunate coincidence? The report by Palmer and Woodall⁷ of 88 deaths in 191 recorded cases of hepatitis associated with cinchophen seems sufficient clinical proof for the hepatotoxic potentialities of this drug in the susceptible patient. MacBryde⁸ states that a number of cases of toxic hepatitis consequent to cinchophen undoubtedly have been mislabeled acute infectious hepatitis. Frequently, as in the case presented above, a history of cinchophen ingestion is not elicited at the initial inquiry.

It has been observed that cholemic nephrosis has received much less attention than the condition merits.⁴ Fahr⁹ described the findings in cholemic nephrosis in some detail in 1925. Ayer's¹⁰ pathological analysis of renal lesions in 18 infants who were jaundiced from congenital biliary atresia is perhaps more comprehensive than any written about this lesion. He consistently found pigmented bile casts in the distal convoluted and collecting tubules in his cases.

In a subsequent study of post-transfusion uremia, Ayer and Gauld¹¹ concluded that the essential features of the renal lesions following fatal transfusion reactions were similar to those seen in the kidneys of infants with biliary atresia. The findings in the kidneys of patients succumbing to subacute epidemic hepatitis also correspond to those described by Ayer.

The tubular lesions seen in our patient also closely paralleled those reported by Ayer in jaundiced infants. Not heretofore described, however, in the nephroses accompanying acute yellow atrophy, acute or subacute epidemic hepatitis, obstructive jaundice or post-transfusion uremia is the presence of a considerable amount of calcium in the cortical collecting tubules and their peripheral branchings and also within occasional distal convolutions. Flocks¹² recently reported asymptomatic pelvic and intrarenal calcium urolithiasis in its early stages. Although its exact intrarenal location is not described, — except within the tubules, — it is presumably located within the collecting tubules and ducts of Bellini in the pyramids. Flocks termed the substance a "phosphate."

What is the mechanism of this calcium precipitation? Several possible causes can be excluded. So far as we were able to determine, the patient had never taken irradiated ergosterol. Except for short periods she had been ambulatory, hypercalciuria due to osteoporosis from immobilization being thus eliminated. At autopsy the parathyroid glands were not conspicuous, nor were there any evidences of multiple myeloma. Urinary stasis, infection and heavy metal intoxication were also absent.

It seems then, that few possibilities remain. So far as we know, the infused methionine solution did not contain significant amounts of calcium salts.

The proximal convolutions exhibited marked albuminous degeneration with a great deal of desquamated detritus and droplets of deep-pink-staining material within the lumen

FIGURE 3 Photomicrograph of the Liver

In the remnant of parenchyma there are regressive changes and vacuolization in the cytoplasm of the liver cells, as well as an inflammatory reaction in the sinusoids and the periportal stroma

Most of the thin segments were dilated and empty, but a few contained red-pink-staining casts. The ascending limbs of Henle's loops occasionally contained similar casts, and

FIGURE 4 Photomicrograph of a Kidney

Note the dilatation of a distal convoluted tubule, with bile cylinders and mononuclear cells within the lumen

rarely a bile cylinder. Bile casts, which were more frequent in the distal convolutions, were rarely associated with 1 or 2 mononuclear cells within the lumen (Fig 4). In several distal convoluted tubules a dark-blue granular substance

appeared. Occasionally, cystic structures were seen—possibly distal convolutions or collecting ducts—lined by flattened epithelium. These contained a similar dark-blue granular substance.

Perhaps most interesting were the lesions in the collecting tubules. The peripheral branchings of the collecting ducts showed rather distinctly dilated lumens with numerous bile cylinders. Many of the collecting tubules in the centrifugal portions of the medullary rays contained considerable amounts of a peculiar, amorphous, granular material similar to that noted in the distal convolutions. This substance, taking a dark bluish-purple color in a hematoxylin-eosin preparation, gave a positive reaction with the von Kossa stain for calcium (Fig 5). With this technic it was apparent that although the bulk of this material lay within the lumen, small amounts were deposited in the cytoplasm of the tubular epithelium as well.

The small capillary vessels of the kidneys showed intense hyperemia, especially in the pyramids. The small arteries revealed moderate sclerotic thickening.

Both lower lobes of the lungs grossly showed distinct flaccid atelectasis, with slight to moderate, apparently in-

FIGURE 5 Photomicrograph of a Kidney

flammatory, edema of the atelectatic parenchyma. Histologic sections showed marked signs of recent pneumonia.

The heart was of normal size and grossly revealed entirely normal chambers, valves and coronary arteries. Histologically, the myocardium showed only slight interstitial edema, with scattered plasma cells and leukocytes, and distinct cloudy swelling of the myocardial bundles.

All other organs, including the pancreas and the thyroid, parathyroid and adrenal glands, were normal. Permission was not granted for examination of the brain.

The findings in the liver in this case correspond well with the classic pathological picture of an acute toxic necrosis. That the disease was of a fulminating character clinically is amply shown pathologically by the severity of parenchymatous damage, the acute inflammatory response and the absence of regeneration or of reactive fibrosis. Reichle,³ in a review of 7 reported cases of death due to cinchophen, to which he added 2 cases of his own, — in

LEUKEMIA CUTIS*

Report of a Case, with a Discussion of Treatment by the Use of Hormones

WILLIAM H. ROBEY, M.D.,† AND G. GARDINER RUSSELL, M.D.‡

BOSTON, MASSACHUSETTS, AND HARTFORD, CONNECTICUT

LEUKEMIA is characterized by hyperplasia of the leukopoietic tissues throughout the body and is usually associated with qualitative and quantitative variations in the circulating leukocytes. *Urticaria*, *pruritus* and *prurigo*, hematomas and actual tumor formations may occur. In the case reported below, the intense skin involvement began early, the leonine appearance of the face and general leukemic infiltration of the skin led to the diagnosis of leukemia cutis—a rare manifestation, only 4 cases having been seen at the Boston City Hospital in twenty years. In association with these skin lesions the blood may remain normal for years or may show only slight changes. Two biopsies early in the disease showed the leukemic lymphocytic infiltration of the lesions.

The case is reported because of its rarity and the effect of hormones on the subjective and objective symptoms.

C. W. P., a 51-year-old married business executive, had always enjoyed perfect health, his habits were excellent, and he kept good hours and used alcohol and tobacco in great moderation.

Late in March, 1942, a slight rash appeared, first on the chest and then on the upper back. No discomfort was felt, nor was there any indisposition. Two or three weeks later, a mild itching developed, increasing sufficiently to interfere with sleep. Gradually, the pin-point spots became confluent, emerging into larger and larger areas until the whole trunk took on the appearance of a mild sunburn. About the middle of June, there was a sharp attack of diarrhea of approximately 12 hours' duration that the patient attributed to food poisoning. A day or so later he noticed a slight swelling of some of the superficial lymph nodes and consulted one of us (G. G. R.).

The itching, especially at night, was increasing but not enough to interfere with the patient's daily activities. The lymph nodes seemed to subside, and there was little change for several weeks. On July 26, the patient played two rounds of golf, which he thoroughly enjoyed, and did not feel fatigued. Two days later, however, he was rather stiff and concluded that his game had brought into play some muscles not recently used. On the following day there was some swelling of the lymph nodes in the groins and axillae. His physician then made a complete physical examination that was stated to be negative, except for the skin and lymph nodes.

Three days later the nodes had increased in size, and the color of the skin had deepened. On August 3 a biopsy was performed, and 6 days later the patient was admitted to the Thorndike Memorial Laboratory, Boston City Hospital, where these clinical findings were confirmed by Drs. W. B. Castle and T. H. Ham. Of particular interest were the raised, nodule-like and hyperkeratotic plaques and the enlargement of the lymph nodes in the submental, cervical, axillary and inguinal areas. The nodes were approximately 1 cm. in diameter, elastic, movable and only occasionally slightly tender. There was doubt about enlargement of the spleen.

Examination of the blood on several occasions disclosed a white-cell count of 9000 to 9600, with 36 per cent adult and 5 per cent band neutrophils, 1 per cent eosinophils, 22 per cent small, 19 per cent large, 8 per cent young and 6 per cent atypical lymphocytes and 3 per cent adult monocytes. The red-cell count was 4,600,000, and on a smear the red cells and platelets appeared normal. The small, young and abnormal lymphocytes had nucleoli, but the cytoplasm did not appear immature. The sedimentation rate was normal, as was an x-ray film of the chest.

The most important diagnostic problem was the interpretation of the biopsy. Dr. Frederic Parker, Jr., did not come to a conclusion on the skin biopsy but made the following comment on that of the lymph node:

The lymph node shows a loss of normal structure for the most part. It is diffusely infiltrated with what appear to be adult lymphocytes. The infiltration also extends into the surrounding tissues. Mitotic figures are fairly numerous. The most probable diagnosis seems to be lymphocytoma, which is consistent with lymphatic leukemia in either the aleukemic or the leukemic phase.

The diagnoses considered were leukemia cutis, Hodgkin's disease of the skin and mycosis fungoides in an early stage. Everything, however, seemed to point to one diagnosis: lymphatic leukemia of the skin, with diffuse erythematous thickening and pruritus, enlargement of the lymph nodes and moderate alteration of the differential count of the blood. A hope was expressed that the course of the disease would be sufficiently slow to permit reasonable comfort and the ability to work.

The proposed treatment consisted of x-radiation of the skin and lymph nodes and the use of Navitol as well as sunlight. Since it was known that some of these cases have been aided greatly by massive doses, the patient was given initially 20 drops of Navitol three times a day and finally 120 drops a day. It was suggested that this treatment be given a trial of from 6 weeks to 3 months with the hope of less itching and possibly some clearing of the lesions. If the Navitol did not help, it might be discontinued and given a trial after a month. Sunlight was to be tried over one area, namely the back, in direct exposure for 10 minutes, the time being increased 5 minutes every other day until there was an opportunity to observe if the area tanned and if the itching was relieved.

On September 29, the patient had taken Navitol in full dosage for 10 days. The skin was becoming a deeper red, more pruritic and in some areas more indurated. The superficial pelvic lymph nodes were more prominent, and a small amount of edema of the feet was observed. Examination of the blood revealed a red-cell count of 3,980,000, with a hemoglobin of 13 gm. (85 per cent), and a white-cell count of 20,450, with 17 per cent neutrophils, 81 per cent normal and abnormal lymphocytes and 2 per cent eosinophils, some of the lymphocytes appeared young. The skin discomfort was more intense. Small doses of Dilaudid probably lessened the itching somewhat and therefore diminished insomnia.

In spite of the x-ray therapy and the doses of Navitol, the patient's discomfort continued to mount, the itching became more constant and violent, the lymph nodes larger and the skin more indurated, and in addition the scrotum and penis were markedly edematous. It was decided to send the patient to the Memorial Hospital in New York City, where he was studied by Drs. C. P. Rhoads and L. F. Craver. The white-cell count at that time was 17,300, and a little later 20,450. The patient was in the Memorial Hospital from October 22 until November 6. At first he received total body irradiation in two small doses, and a single dose of 200 r was subsequently applied to each of the six external lymph-node groups.

Unfortunately, however, a blood calcium determination was not made. We are unable to say whether or not the amino acid itself produced precipitation of the calcium salts, or even tubular necrosis.

The renal picture was interesting because of its clinicopathological correlation. The bladder was empty at post-mortem examination, despite ample fluid therapy. In spite of this anuria, however, the terminal blood urea nitrogen was 15 mg per 100 cc. With severe hepatic dysfunction producing a decrease in urea formation, this figure probably falsely implies normal renal function. In view of a urea nitrogen value of 11 mg three days previously and adequate parenteral fluids in the interim, it may have indicated early renal retention. A phosphorus determination in this particular case is more significant, for urea and creatinine figures probably mean little. Indeed, a significant rise of the serum phosphorus did occur concomitant with the development of anuria.

Urinary suppression was not present in Wilbur's¹³ cases of bile nephrosis. Nor was there clinical evidence of renal insufficiency in Ayer's¹⁰ infants with congenital biliary atresia. Although clinical renal failure was apparent in Ayer and Gauld's¹¹ cases of post-transfusion uremia, the morphologic alterations were essentially similar to those seen in the jaundiced infants. It was therefore considered unlikely that the morphologic changes in the kidneys after delayed reaction to transfusion were responsible for the renal failure observed clinically.

In the case presented above, however, the pattern of the kidney lesions seems significant. The calcium was present in considerable amounts in numerous tubules. The bile cylinders were situated proximal to the precipitated calcium. Furthermore, the tubular system proximal to the segments impregnated with calcium showed dilatation, whereas distally there was none. Histologically, therefore, there seems to have been evidence for an obstructive factor in the anuria in this case.

In their search for criteria for the safe administration of cinchophen, Palmer and Woodall⁷ were forced to admit the absolute unpredictability of its action. They found no method of administration that ensured against a fatal result. Previous ingestion, the absence of a history of allergy, the age and sex of the patient and even the dose seem to be of little value. In our case, for example, there was no history of allergy, the patient was a young child, and such as hepatic regenerates, and the absence of pre-existing disease is important, for it is well known that the liver has a considerable reserve from previous

FIGURE 4 Photomicrograph showing the dilatation of a distal convoluted tubule and mononuclear cells within the lumen.

rarely a bile cylinder. Bile casts, which were in the distal convolutions, were rarely associated with mononuclear cells within the lumen (Fig. 4). In distal convoluted tubules a dark-blue granular substance

liver disease, although it cannot exclude possible sensitization due to previous ingestion of cinchophen.

We have personal knowledge of at least 2 patients who developed urticaria following the ingestion of a single tablet of cinchophen. Short and Bauer,¹⁴ influenced by a study of 41 cases, considered this urticarial reaction an absolute contraindication to further cinchophen administration. Fink and Gay¹⁵ reported cases of urticarial rashes as long as three months after the discontinuation of atophan.

The usage of cinchophen is no longer widespread. If it must be employed, it should probably be reserved for the patient with severe gouty arthritis, especially in the interval between the acute attacks. Colchicine remains the drug of choice for the acute attack of gouty arthritis.

Our case of acute yellow atrophy beginning on the day after the ingestion of 2 gm of cinchophen terminated fatally twelve days later. The gross and histologic findings in the liver differed in some respects from those reported in cases of acute or fulminating hepatitis. Clinical and pathological evidence of pre-existing hepatic disease was absent. Urinary suppression and early phosphorus retention were featured. In addition to the usual picture of cholemic nephrosis, the kidneys showed considerable amounts of calcium within the collecting tubules and their peripheral branchings.

Sections of the lymph nodes showed extensive destruction of the normal architecture by uniform infiltration of the dull appearing lymphocytes, typical of lymphatic leukemia.

Microscopical examination of the skin showed that the corium was extensively infiltrated by lymphocytes, a typical leukemic reaction. The remainder of the picture was consistent with lymphatic leukemia.

* * *

When this patient was seen at the Hartford Hospital in late January, 1943, he had a temperature of 103°F and was disoriented, the eyes were the only recognizable feature, and the end seemed imminent. Since there was a chance that female hormones

might be of value, other forms of treatment (Navitol and x-radiation) having been of no avail, Progynon was begun at once, and steady progress occurred until, in August, 1943, there remained only slight serous oozing about the ankles.

It may be argued that this case of leukemia cutis might have improved under some other treatment, or possibly with none. As a matter of fact, the symptoms diminished only with the use of hormones. If a similar case is seen, treatment with hormones certainly deserves serious consideration.

MEDICAL PROGRESS

EFFECTS OF PROTEIN DEFICIENCY ON THE PREGNANT WOMAN AND FETUS AND ON THE INFANT AND CHILD*

HAROLD C. STUART, M.D.

BOSTON

MANY of the ill effects of a lack of sufficient or suitable proteins in the diet are encountered at all ages and in both pregnant and nonpregnant women. Some of them are particularly likely to occur during pregnancy, and others at certain periods of rapid growth in childhood when requirements are exceptionally high. The specific syndromes resulting from protein deficiency are not reviewed below, but attention is given to certain other effects that appear to be associated with pregnancy, with the health and development of the fetus, and with the progress of growth and development in infancy and childhood.

In the discussion of a single nutritional essential it must be kept in mind that except under conditions of rigid experimental control, attainable only in studies of animal nutrition, there are always many variables. For example, a diet low in protein is likely to be lacking in other essentials as well. Furthermore, the requirement for protein is modified by other characteristics of the diet. In some of the studies reviewed below the part played by protein is only implied, sometimes quite logically on the basis of all the known facts but at other times as a hypothesis to stimulate further study. For example, a woman who eats poorly and hence obtains too little protein may do so because of ignorance, disease or lack of money or because she is in a poor physical or psychologic state. Many other factors, therefore, must be considered, and supporting evidence is still required before one can conclude that protein per se is concerned with or primarily responsible

for certain complications of pregnancy or conditions of infants at birth that have been found to occur much more frequently when the maternal diet has been poorly provided with protein than when liberally provided. Also, a child who is constitutionally inferior may grow or develop in an unsatisfactory manner, not primarily because he eats a generally poor diet or one lacking in protein but because constitutional inferiority contributes both to poor appetite and to poor progress in growth and development. Again, it may be difficult to establish whether or not the poor physical state and progress are related to a poor nutritional background, and if so, whether inadequate protein is the principal dietary factor involved.

PROTEIN DURING PREGNANCY AND LACTATION

Increased Requirements

Several nitrogen-balance studies¹⁻⁴ have shown that women normally store relatively large amounts of protein during pregnancy. This positive nitrogen balance, according to Wilson⁵ and Macy and Hunscher,⁶ begins about the tenth or twelfth week of gestation and increases to term. Part of the protein is needed for the development of new maternal tissues, such as the breasts and uterus, and part is utilized in building the tissues of the fetus, including the placenta and membranes, but the total stored is in excess of these needs. The average fetal body at the sixth lunar month has been found to contain only 8 gm of nitrogen, whereas at term it contains 60 or 70 gm.^{1,2} The membranes and fluid at term contain about 19 gm, making a total for the mature ovum of 79 to 89 gm. An additional 17 gm of nitrogen is required on the average for the development of the mammary glands and 39 gm for the

On November 20 the patient weighed 166 pounds — this fact is mentioned because of the marked variations in weight, depending on the induration of the skin and the intensity of the edema. The skin over almost all the body was described as a "horrible brownish red." The patient was more animated and was working a part of each day. There were some large nodes in the groins, smaller ones in the axillae and still smaller ones about the jaw and the posterior chain in the neck. The spleen and liver were not palpable. The leonine expression of the face was striking, the color of the skin was a magenta red, and one of the most distressing symptoms was the constant itching, which made it impossible to refrain from scratching the face and head, especially the ears, which were greatly enlarged.

Examination of the blood at that time revealed a red-cell count of 4,310,000, with a hemoglobin of 13 gm (88 per cent), and a white-cell count of 20,600, with 9 per cent neutrophils (3 per cent myelocytes and other forms showing many toxic granules), 80 per cent lymphocytes (25 per cent large young forms and 55 per cent small forms) and 11 per cent smudges — probably lymphocytes. A subleukemic leukemia could not be excluded on this examination.

Navitol, which had been given daily in full doses of 150 drops, was discontinued, since it did not seem helpful and the patient thoroughly disliked it. The skin was much indurated, and the oozing from various areas required careful dressings each morning. No material change in the blood picture had occurred.

On January 30, 1943, the patient was seen in consultation by one of us (W H R) at the Hartford Hospital. He was disoriented. The temperature was 103°F. The skin, even on the scalp, was a dusky red, and much of the hair had dropped out, leaving only small scattered tufts, the nails had degenerated. There were oozing areas in which the itching was intense. The patient was so ill that he was given oxygen inhalations.

The use of female hormones was suggested, and treatment with Progynon B was immediately started in increasing doses, all forms of x-ray therapy were stopped.

There was marked edema, which raised the body weight to a maximum of 220 pounds and was relieved to a slight degree by a mercupurin suppository. On February 6 the edema had largely disappeared. The chest had become clear, and oxygen had not been given for 5 days. The weight had dropped from 220 to 190 pounds. The inguinal and axillary lymph nodes seemed to be somewhat larger and harder. The liver and spleen could not be felt. The loss of edema was remarkable. Navitol had been stopped for a week, but Progynon had been continued.

At that time the main problem was respiratory. Greater difficulty in breathing and rales over the entire chest persisted for several days before x-ray examination was performed. The lungs showed congestive changes and patchy areas of increased density, without evidence of lymph-node enlargement, that were interpreted as being due to infiltration of the lung tissue and to edema similar to that in the skin. X-ray treatment was considered valueless, and for several days oxygen was again administered. The skin and subcutaneous tissue had become definitely less edematous. The temperature was moderately elevated — 101 to 102°F. It was thought that Progynon might be credited with the weight loss. The patient seemed more comfortable, but although lucid at times, he was often confused and did not remember anything about the previous consultation.

On March 11 examination of the blood showed a hemoglobin of 81 per cent and a white-cell count of 28,100, with 31 per cent neutrophils, 65 per cent lymphocytes, 3 per cent eosinophils and 1 per cent monocytes. Ten per cent of the lymphocytes were young forms. The skin was continually desquamated and itchy. The circulation seemed adequate, and the urine was normal.

On March 25 diethylstilbestrol was added — in doses of 0.5 mg at first and subsequently 1 mg three times daily, the Progynon was administered as previously. Obundant ointment did more to relieve the itching than anything that had been tried. Early in May the whole condition showed improvement.

At the end of June the weight was 152 pounds, and the edema had practically disappeared except in the upper thighs, the scrotum was normal. The nails were growing, but the patchy baldness remained. There were some lymph nodes in the axillae and thighs. The liver was much smaller. The

skin over the entire body had become lighter in color. The breasts were slightly conical, and for that reason the dose of stilbestrol was reduced by half.

The hemoglobin was 11.7 gm (75 per cent), and the white-cell count 4200. A blood smear showed few white cells, the red cells approached normal in appearance. The platelets were small but numerous. In the stained specimen no abnormal cells were seen. The patient was anxious to be out and about, but since the thighs and legs were still large and heavy, walking was laborious.

On September 14, after making a motor trip of 120 miles, the patient arrived at his destination without undue fatigue, and his whole appearance was almost incredibly normal and healthy. The skin was clear and smooth, the hair had grown, and the appetite was excellent. Except for slight swelling about the ankles there was nothing unusual in his appearance.

In October the patient had recovered sufficiently to resume business on a half-day basis, he played eighteen holes of golf with ease, and his spirits were high. Stilbestrol had been discontinued for about 4 months, but Progynon had been taken, with a steady improvement in vigor and appearance. His condition was so satisfactory, even to complete freedom from desquamation in the legs and feet, that Progynon was stopped 3 months later.

On January 14, 1944, the patient developed a fine petechial rash over the chest and shoulders that was quite different from the original smooth erythema observed the year before. Although the hormones had not been given except in small doses for several weeks, the condition remained much improved, and the rash diminished after the Progynon was resumed in full doses. The blood picture was normal. A few young white cells were seen. On February 17 the patient saw Dr Craver, who considered the results in this case remarkable and who stated that resumption of Progynon was indicated in view of the reappearance of erythema in patches since its discontinuance.

On March 21 the condition was worse, the rash was confluent and the skin indurated.

In June, after a long course with Progynon, diethylstilbestrol and vitamins, the weight, which had risen in the preceding months, was reduced to 170 pounds, remaining at that level. There was little tendency to purpura, and the exudation was limited to the feet. The patient was considered definitely improved.

The rash seemed to be influenced by Progynon, for the petechial character became less marked and less brilliant. Since the rash seemed to the dermatologist and to the patient's own physician to be of quite a different character from that of the original, it was the desire of the dermatologist to discontinue the hormones for a time to see what effect purely local treatment would have. In July, however, the lymph nodes became larger, and the induration of the skin more marked. The edema and oozing increased. With all these changes the blood picture remained essentially the same. On September 6 another consultation took place while the patient was still at home. He was a dark red oozing mass, itching constantly and generally miserable. Three days later he was sent to the Hartford Hospital, where, on September 14, he died suddenly before the resident could reach his room. The manner of death suggested pulmonary embolus.

Autopsy. The anatomical diagnoses were chronic lymphatic leukemia, with leukemic infiltration of the spleen, liver, kidney and bone, leukemia cutis, thrombus in the right iliac vein, pulmonary embolus, with an infarct of the right lung, thrombus in the left renal vein and chronic cholecystitis with cholelithiasis.

The skin over the body showed a most remarkable appearance. Everywhere, from head to foot, it had a deep-red, scaly, thickened appearance. This was most prominent over the lower extremities, although it involved the upper chest, arms and face. On the lower extremities there were areas of ulceration between zones of thickened, scaly, red skin. These ulcerated areas, particularly those on the medial aspect, had a moist appearance. The skin on palpation had a brawny induration. The right leg was rather markedly edematous, and the left was atrophic in appearance. There was a moderate edema of the scrotum and penis. The skin was inelastic and thickened, and there was a diffuse edema of the subcutaneous fatty tissue, thin fluid exuded when the tissue was incised. The breasts appeared enlarged and when sectioned showed rather marked hypertrophy. The axillary lymph nodes were greatly enlarged, measuring up to 3 to 4 cm in diameter, they were of a soft consistence and had a pink appearance.

lactation About one and a half times the amount of protein secreted in the milk is needed in the diet to provide for this—that is, about 25 to 30 gm per liter of breast milk. The National Research Council's⁹ recommended allowance for the lactation period is 100 gm of protein daily—40 gm above that of the nonpregnant, nonlactating woman. This allowance seems to be liberal and sufficient to allow for individual differences in requirement and utilization. Various reports from famine areas indicate that when women are markedly underfed, they are unlikely to produce an adequate supply of breast milk. Protein deficiency appears to be an important factor, although probably not the only one involved in these situations. Garry and Wood¹⁶ have suggested that the negative nitrogen balance frequently encountered in lactation may be conditioned by an energy intake too low for all the demands made on the lactating woman. Since the caloric requirement is markedly increased during lactation, it is clear that calories as well as protein must be considered. The successful nursing mother has been shown by Kaucher¹⁷ to select usually a high-protein, high-calorie diet. Emotional instability is likely to affect the appetite adversely and is detrimental to successful nursing.

On the basis of these considerations, it seems to be important that a woman end pregnancy with liberal stores of nitrogen, and that she consume in the neighborhood of 2 gm of protein per kilogram of body weight, or about 100 gm a day, during lactation.

Effects of Maternal Protein Deficiency

Conception rate Before the effects of low protein intake and generally deficient diet on the pregnant woman and the fetus are considered, it should be pointed out that severe dietary deficiency leads to amenorrhea and inability to conceive. This is a well established result of gross underfeeding in animals and one that must be considered in all animal experimentation. It has been found to have occurred in a number of areas where human starvation was in progress. According to Smith,¹⁸ whose interesting observations are further considered below, the conception rate in Holland during the hunger winter of 1944–1945 fell to 30 per cent of normal. How much of this was due to absence of husbands and how much to malnutrition cannot be determined, but the latter was clearly a major factor. Sixty per cent of the women of menstrual age in the large cities of Holland developed amenorrhea, and there was a correspondingly sharp fall in the birth rate. Antonov¹⁹ also reported a marked fall in the birth rate in Leningrad during the siege. Sydenham²⁰ recently reported the occurrence of amenorrhea among British civilian internees in the Stanley Camp at Hong Kong, China. During the months in which the diet was low in protein but adequate in calories, many women remained amenorrheic

without losing weight. The incidence of amenorrhea fell sharply after supplies of tinned meat became available through Red Cross shipments. Sydenham concluded that although emotional shock or change of environment may have explained many of the irregularities of menstruation and the early cases of amenorrhea of short duration, the 53.7 per cent of patients with amenorrhea lasting more than three months—in some cases lasting a year or more—could hardly be explained on this basis. Malnutrition, especially deficiency of protein, appeared to be the most probable cause.

Complications of pregnancy Williams¹⁰ has recently reviewed the relation between protein nutrition and the course of pregnancy. He refers to the customary evidence of protein deficiency, such as depletion of body tissues, lowered serum protein, nutritional edema and lowered resistance to infections. Although these manifestations of protein deficiency occur more frequently under the stress of pregnancy, they are not peculiar to this state and are therefore not considered here. Williams considered at greater length the possible relations between protein nutrition and toxemia, the anemias of pregnancy, poor uterine muscle tone and lowered resistance to special infections during the puerperium. These may be regarded as the more particular problems of protein malnutrition affecting the health of the woman during pregnancy.

Since the cause of toxemia of pregnancy is still obscure, one who is not an obstetrician hesitates to discuss this complicated subject. Recent studies of Smith and Smith²¹ point to a true toxin resulting from damage to the uterine tissue associated with abnormal estrin-progestin metabolism. Nevertheless, it may be accepted that the ultimate cause of this complication of pregnancy remains to be established, and it seems clear from several recent studies that protein metabolism is a factor of possible significance. Unquestionably, many influences are concerned, but this review restricts attention to the evidence regarding the relation of dietary protein to the incidence of toxemia.

A number of workers^{11, 22–27} have presented evidence that the incidence of toxemia is far higher among women whose intakes of protein are markedly deficient or whose diets are generally poor than among those whose diets are generally good or are well supplied with protein. The difficulties involved in human studies in proving whether or not a given nutrient is responsible for a given effect are apparent to those who have attempted to investigate these relations further. Strauss²² has contended that the most plausible assumption is that in the presence of protein insufficiency the colloid osmotic pressure of the serum protein is altered. This causes edema and a consequent disturbance in the electrolyte balance that, in turn, results in elevation of the blood pressure and other symptoms of toxemia. In such circumstances, protein may serve as a protec-

uterus,⁵ making 56 gm the amount needed on the average for the growth of maternal tissues. On the basis of these findings, it has been estimated that about 135 to 145 gm of nitrogen beyond maintenance needs is required during pregnancy, or about 845 to 900 gm of protein.⁷ Macy and Hunscher⁶ and Wilson⁵ have shown that under favorable circumstances the amount of nitrogen actually stored is 200 to 400 gm, representing 1250 to 2500 gm of protein, in excess of the probable utilization by the mother for herself and for the fetus in the replacement of old tissues or the construction of new.

A negative nitrogen balance sets in abruptly just before term,⁶ and there is a substantial loss of nitrogen from the maternal organism during parturition and the post-partum period. For women who nurse their infants, there is an additional loss in the breast milk amounting to about 1 to 1.5 gm of nitrogen a day, depending on the amount of milk secreted. Thus, it is usual to find a negative nitrogen balance throughout the puerperium, and often during the lactation period as well. The reserve of nitrogen stored during pregnancy, therefore, may be regarded as in part a natural mechanism to provide in advance for the large losses occurring during delivery and the puerperium, and in part for the high requirements of lactation.

The actual increase in dietary protein required to meet the needs of pregnancy is a matter of debate. From the calculations regarding nitrogen requirements discussed above and from studies by Burke et al.⁸ of the condition of the infant at birth in relation to the level of maternal dietary protein, an increase in the protein of the diet during the last six months of pregnancy of 15 to 20 gm a day above the woman's normal requirements may be assumed to be the average need.

If it is assumed that an allowance of 60 gm of protein is desirable and adequate for the average nonpregnant woman and that an increase of 15 to 20 gm daily is needed for these special purposes in pregnancy, the allowance recommended by the Food and Nutrition Board of the National Research Council⁹ of 85 gm during the latter part of pregnancy seems to be liberal and sufficient to take care of individual differences. Williams,¹⁰ in a review of this subject, emphasized the important point that this figure presupposes a previously normal protein intake and nutritional state.

The question immediately arises of how nearly the diets of pregnant women approximate this allowance. Burke,⁸ in studies at the Boston Lying-in Hospital, found that the diets in 68 per cent of 216 pregnant women contained less than 70 gm, those in 38 per cent, less than 55 gm and those in 14 per cent, less than 45 gm of protein daily. Arnell¹¹ in studies of 400 pregnant women in New Orleans found that 18 per cent took less than 42.5 gm of protein daily—that is, less than half the allowance recommended by the National Research

Council—and 79 per cent less than 70 gm. In dietary studies on 514 pregnant women in Philadelphia, Williams¹² found that only 13 per cent were taking 85 gm of protein daily as recommended. Since many women habitually take a poorly balanced diet that is low in protein and do not change their habits appreciably during pregnancy, it is not surprising that the usual signs of protein malnutrition are encountered more frequently when the physiologic strain of pregnancy is superimposed on normal requirements.

The need for protein in the mother's diet during lactation has received considerable attention. In the dairy industry the value of a liberal intake of protein during the latter part of gestation for successful milk production has long been recognized.¹³ In women, psychologic factors have such an important influence on milk production that the relation of diet and nutrition to milk supply is difficult to demonstrate. The evidence suggests that diet during pregnancy—and possibly before—has at least as much to do with a satisfactory supply of breast milk as the diet during lactation. Macy and her associates¹⁴ have shown that a high-protein diet during the latter part of pregnancy is important for successful nursing, and that a diet high in animal protein results not only in the highest nitrogen retention but also in the highest milk yield.

Orr and Gilks¹⁵ studied lactation and growth in a South African tribe that lived principally on cereals, roots and legumes and lacked milk and other suitable infant foods. The mothers in this tribe were unable to nurse their babies successfully for an average of more than three months, and after three months the infants grew poorly. In contrast, the mothers of a pastoral South African tribe, living mainly on animal foods, continued to nurse their babies successfully for long periods. The differences in size and physique of the infants of these two tribes became progressively more striking from three months onward.

Without going farther into the details of the controversial literature on the relation of diet and nutritional status to lactation, the following tentative generalizations seem to be justified. Women differ considerably in their capacity to develop breast tissue, and the development of the breasts during pregnancy may be further restricted by chronic malnutrition or by a lack of adequate protein. The quantity of milk that any woman secretes is determined only in part by breast development, for it is influenced by mechanical, psychologic and nutritional factors. Under favorable conditions a woman secretes milk at the expense first of the dietary protein and then of the protein tissues. She continues to do so for long periods, with a resultant negative nitrogen balance. How long or successfully she will secrete an adequate supply depends in part on the protein intake and nitrogen storage during pregnancy, as well as on the protein intake during

They believe that it is probably dependent on a lack of complete proteins but possibly also on a deficiency of one or more of the factors in the vitamin B complex. This type of anemia usually responds to an increased intake of animal protein and of the factors of the vitamin B complex.

Labor and delivery. There is little evidence that protein deficiency in the mother contributes directly to prolonged or difficult labor and to other complications at or following delivery. Poor development of the uterus was found by Wallace³¹ to be a striking end result of low protein low-calorie diets in sheep. Uterine inertia and prolonged labor have often been considered attributable in individual cases to poor nutritional state. In the studies at the Boston Lying-in Hospital the average length of labor of the primiparous women was the same in the group with poor diets as in that with good diets.²² It is of interest, however, that in this series of 216 cases there were many more difficult types of delivery in the patients with poor to very poor diets than in those with good or excellent ones, despite the fact that the infants in the former group were on the average 3 pounds lighter in weight. It is generally recognized that large babies make for more difficult deliveries than small ones do. Hence, other things being equal, the mothers with poor diets should have had shorter labors and easier deliveries. The assumption may therefore be made that the women in the poor-diet group were not otherwise so fit for labor.

Frequency of abortions and stillbirths. Arnell,¹¹ in the studies referred to above, showed that when the maternal dietary protein was 85 gm or more there was no fetal mortality and that when it was between 70 and 85 gm daily the mortality was only 2.2 per cent. On the other hand, when the protein consumed was between 42.5 and 54 gm, the fetal mortality rose to 5.5 per cent. In another report of the 216 cases referred to above,²² there were no abortions probably because enrollment was not until the end of the third month or later. There were, however, 5 stillbirths, all of which occurred in pregnancies of women with very poor diets. All the women whose babies were stillborn consumed diets that were inadequate in protein, and in all but 1 case the calories were rated inadequate. Two of the 3 neonatal deaths in this series also occurred in the group with poor to very poor maternal diets. Ebbs⁴ found that of the 14 infants lost in a total of 310 pregnancies, all were in the group with poor maternal diets. There were 7 miscarriages, 4 stillbirths and 3 neonatal deaths in his series. Williams,¹² however, found no relation between maternal diet and the condition of the infant at birth.

Smith's¹⁸ data from Holland are inconclusive on these points as are the figures of Antonov,¹⁹ which cover the period of the siege in Leningrad. It is impossible to draw conclusions from changes in rates representing proportions of live births, when

the birth rates were changing as rapidly as they were in Holland and Leningrad at the times of these studies.

Premature births. In our studies in Boston all prematurely born babies — that is, infants weighing less than 2.25 kg (5 pounds) at birth — were born to mothers whose diets were in the lowest general rating. Here again, the work of Ebbs,²⁴ the Peoples League of Health²⁵ and Balfour,²⁶ showed the same trend, but that of Williams¹² failed to do so. Smith¹⁸ also found a slight but not statistically significant increase in the percentage of births of infants weighing under 2.25 kg during the hunger period in Holland. Antonov¹⁹ observed that the rate in Leningrad was 41.2 per cent of the total births during the siege but fell to 6.5 per cent in the first

TABLE 1. *Relation of Birth Weight and Length to Total Protein in Maternal Diet during Last Six Months of Pregnancy (according to Barke et al²⁷)*

AVERAGE TOTAL PROTEIN ^a	BIRTH WEIGHT*		BIRTH LENGTH	
	MALE INFANTS	FEMALE INFANTS	MALE INFANTS	FEMALE INFANTS
	lb	oz	cm	cm
Less than 45	6	8	47	46
45-54	7	0	49	48
55-64	7	7	50	49
65-74	8	0	51	50
75-84	8	5	52	51
85 and over	9	2	53	52

*No infants weighing under 5 pounds included.

six months after it had ended. The marked reduction in the birth rates during these periods complicates the interpretation of these figures as they do those for abortions and stillbirths.

The evidence suggests that inadequate protein during pregnancy, especially when enhanced by inadequate calories, increases the chances of premature onset of labor. Again, it must be concluded that although poor maternal diets and a high incidence of abortions, stillbirths, premature births and neonatal deaths are frequently associated, the nature of this relation is not yet known.

Size and development of the infant at birth. The evidence regarding the association between maternal diet and the size and development of the infant at birth is much stronger and more convincing than that for the relations thus far considered. It is difficult to separate exactly the infants who are small and poorly developed at birth because of premature onset of labor and those who have reached full term showing evidences of retarded fetal growth and development. The former is primarily a maternal effect, and the latter a fetal one. For this purpose premature birth is usually determined arbitrarily on the basis of a selected birth weight, and in our studies a weight of 5 pounds has been used. Table 1 presents birth weights and birth lengths according to the quantity of protein in the maternal diet during pregnancy.

tive or therapeutic agent by virtue of its chemical and physiologic properties, rather than as a source of building materials for new tissues, as in most of the situations being considered

Studies of pregnancies in 216 cases have been reported by Burke and her associates²⁷ at the Harvard School of Public Health. The patients were followed at the Boston Lying-in Hospital, with detailed dietary histories each trimester, and the diets were graded into five categories from "very poor" to "excellent." There were 28 cases of toxemia in the series. The incidence of this condition was 44 per cent among the patients whose general diets were rated "poor" to "very poor" and 8 per cent among those rated "fair," whereas among those rated "good" or "excellent" not a single case developed. This association between generally poor diet and high incidence of toxemia is impressive and has statistical significance, but when analyzed on the basis of protein alone the relation was not statistically important, although in the same direction. The number of cases is too few to justify conclusions, and further study is required. Arnell¹¹ found a higher incidence of toxemia among patients with a low-protein diet than among those with a liberal protein diet. Holmes²² reported that the incidence in groups of 350 primiparous and 350 multiparous women taking low-protein diets was twice as great as that in similar groups taking high-protein diets. On the other hand, Dieckmann²⁸ could not confirm this relation and has expressed the view that toxemia and a low-protein intake are not related.

Reports from certain areas in which true starvation occurred during World War II, as well as during World War I have indicated that the incidence of toxemia fell sharply among pregnant women during the periods of extreme food restriction. In studies of pregnancies and their outcome at the midwifery school of Rotterdam, Holland, before, during and following the acute famine of 1945, Smith¹⁸ obtained rather surprising figures regarding the incidence of toxemia. During the months of acute hunger the incidence fell to about half that occurring in the same institution during the pre-hunger and post-hunger periods. The diets of pregnant women from January to April, 1945, of the so-called "hunger winter" provided according to the ration figures approximately 750 to 900 calories and 35 to 40 gm of protein. Although there is no way of knowing how much additional food these women may have had, it is safe to assume that even at best the diets during this period were low in both calories and protein, as well as in minerals and vitamins.

The studies of the results of war shortages on toxemia are in such sharp contrast to those of other maternal dietary studies that one must examine the data carefully for an explanation of the differences. In Holland the hunger period was one of brief duration, rarely affecting more than half of any pregnancy, and the pre-hunger period provided rela-

tively good nutritional circumstances. The more detailed dietary studies in the United States, in contrast, indicate that the women with poor diets for the most part had habitually consumed such diets before and during pregnancy. In Holland the hunger diet was one of low calories and roughly parallel reduction in protein and other essential nutrients, whereas in this country the poor diets were usually poorly balanced providing more or less adequate, sometimes excessive, calories drawn largely from classes of foods that carried little protein and other structural and regulatory essentials. A factor that may have influenced the results in Holland was the sharp fall in the conception rate. It could well be that the women in Holland who were chronically undernourished, and hence presumably predisposed to the development of toxemia, became amenorrheic in a relatively short time on such an inadequate diet and hence did not conceive. The potentially toxemic women may thus have been removed temporarily from the population of the maternity hospital.

Although there is still controversy among well informed persons concerning the cause of toxemia, it is generally accepted that a high-protein diet does not predispose the patient to the condition. Furthermore, the major weight of evidence appears to be that toxemia occurs oftener among chronically malnourished than among well nourished women, protein being one of the nutritional factors frequently lacking. Most workers, including those in my group and others who have obtained similar results, are agreed that although definite conclusions cannot yet be drawn the subject is an important one for further investigations.

Anemias of pregnancy. A physiologic reduction in the number of red cells and in the hemoglobin takes place normally in midpregnancy and is apparently a dilution phenomenon. The hypochromic anemia often seen in late pregnancy is generally considered to be an exaggeration or prolongation of this physiologic change. Bethell,²⁹ reporting a 25.4 per cent incidence of anemia in a group of 484 pregnant women in Michigan, found a relation between deficiency of dietary iron and hypochromic anemia. This type of anemia often responds poorly to iron therapy alone and has been reported to respond much more satisfactorily to a combination of a diet high in animal protein and medicinal iron.

True macrocytic anemia of pregnancy is rarely encountered in this country. Bethell, in the study mentioned above, found a relation between macrocytic anemia and an inadequate intake of protein. Severe macrocytic anemia of pregnancy is reported to be frequent in India. This type of anemia carries with it high maternal and high fetal mortality rates. Napier and Neal-Edwards,³⁰ who have studied the condition extensively in India, point out that its incidence is highly correlated with a low economic status and with diets low in protein of animal origin.

CASE 33141

PRESENTATION OF CASE

First admission. A nineteen-year-old unmarried girl was admitted to the hospital because of pain in the lower back.

For three years the patient had suffered from pain over the coccygeal region. The pain was nonradiating and was aggravated by long sitting or standing, but was not noticeably increased by rising or sitting down. She had noticed some tenderness and pressure over that area. A year prior to admission a pilonidal sinus had been removed from the area, without relief from pain. She suffered a great deal from riding in an automobile and sitting in a soft seat, and the pain was often worse at night.

No contributory past history was obtained.

On physical examination the only positive finding was pain on pressure over the coccygeal region and just to the right of the scar from the operation for pilonidal sinus. Examinations of the blood and urine were negative, except for a white-cell count of 12,700. The differential count was normal. A blood Hinton test was negative. X-ray films taken in the Out Patient Department before admission revealed the coccyx to be poorly visualized and somewhat fragmented. There was a faint suggestion of a soft-tissue mass, measuring 5 cm., in the midline, at the extreme distal tip of the coccyx.

X-ray examination on admission revealed that the lower segments of the coccyx were absent. The previous films were not available for comparison.

While in the hospital the patient noted a small amount of mucus in the stool and stated that she had noticed this once or twice about two or three months previously. She denied any pain during bowel movements. There had never been any blood in the stools, although the mucus had once been slightly pink. After sigmoidoscopic examination the pain disappeared completely, and the patient was surprised at her ability to lie in any position. Three days later the pain was still only mild. A psychiatrist discovered considerable emotional problems relating to the family. He thought that the patient was somewhat emotionally immature. The mother was domineering, and there was competition with a brother for parental affection. Study on the psychiatric service was recommended. The patient was discharged with instructions in gluteal exercises and sitting.

Final admission (five months later). The patient was followed in the Psychiatric Out Patient Clinic without improvement. Five months later she was noted to have erythema and induration in the region of the scar, possibly as a result of excessive physical therapy. She was noted to be stooping somewhat and was again admitted to the hospital. She localized the pain largely to the tip of the sacrum. No mass was felt by several examiners. Examinations of the blood and urine were negative. An x-ray film revealed that the coccyx and lower segment of the sacrum were missing and there was a soft-tissue mass, measuring 7 by 4 cm., within which there were areas of calcification or bone remnants. The edge of the remaining segment was somewhat ragged. Subsequent to this report an extremely hard, tender mass was palpable by rectum or pelvic examination corresponding to the x-ray finding at the lower end of the sacrum. An x-ray film of the chest was negative. The blood calcium was 8.9 mg., and the phosphorus 3.3 mg. per 100 cc., and the phosphatase 15.7 Bodansky units.

About a month after admission an operation was performed.

The progressive increase in average birth length and birth weight with increasing amounts of dietary protein during the latter part of pregnancy is striking

Smith,³³ in his study of birth weights and birth lengths in Holland, found a sharp drop during the hunger winter and an almost equally abrupt rise as Holland emerged from the period of severe malnutrition. This association between the size of the newborn and the adequacy of rations may well have depended on the protein content of the maternal diet as well as on the caloric content, since the Dutch diets were known to be low in protein during this period and since low calories make the diet even less satisfactory in protein. In studies of babies born in Leningrad during the siege, Antonov¹⁹ showed similar trends in birth weights, the average during the first half of 1942 being approximately 0.5 kg. lower than that for the corresponding period of 1941 before the siege. During the second half of 1942 (after the siege), the average weight had risen about half the amount lost.

Wallace³¹ has shown that when the diets of sheep are made low in calories and protein in the last half of pregnancy the weight and length of the newborn are markedly lowered. Using the same mother animal Wallace reversed the results by increasing these components of the dietary intake of the pregnant animal. Whereas it is not possible to say from these experiments that protein was the only factor responsible for the differences in the rates of growth of the fetuses, it is possible to conclude that the combined intake of calories and protein in the latter part of pregnancy was the primary variable.

The relations found by my associates in Boston, the evidence of Smith from Holland, the work of Antonov in Leningrad and recent English studies reviewed by Garry and Wood¹⁶ provide strong evidence that if the diet is low in protein during the latter part of pregnancy, there is a tendency for the infant to be born prematurely or to be relatively immature at birth.

Evidence of retarded osseous development in infants born to mothers whose diets were poorly provided with protein has been presented.³⁴ Osseous ratings of "advanced," "average" and "retarded" were given on the basis of the presence or absence of certain osseous centers at birth in roentgenograms of the knee, hand and foot. When the maternal diet was excellent in protein, 57 per cent of infants were advanced in osseous development, and 14 per cent retarded, whereas when the maternal diet was very poor in protein no infants were advanced and 71 per cent were retarded. Although this relation appears to be significant, it must be remembered that certain other nutrients closely associated with protein in food may have been involved. It is known, however, that protein forms the matrix for bone growth, and there are other reasons for

believing that protein may be the principal factor. Wallace³¹ has presented data on sheep that tend to confirm this relation. He found much poorer skeletal formation in the young of the sheep inadequately fed in protein and calories in the latter part of pregnancy than in those well fed during this period.

The studies of Wallace referred to above showed that changes occurred in the maternal stores of protein in conjunction with changes in the diets. His results indicate that the fetus is parasitic on the mother only to a degree and that when her protein stores are depleted to any major degree she appears to retain the remaining stores as if some protective mechanism were operative. These studies also show that when the maternal animals are starved in relation to calories and protein in the latter part of pregnancy the livers of the young are small, the increase in size during the last half of pregnancy being approximately 8 per cent of normal.

(To be concluded)

the patient has had no subsequent difficulty. Although this is a rare location for a benign giant-cell tumor, it is a possible one.

Dr. Simmons, have you anything further to say?

Dr. SIMMONS: In any of these cases in which the radiologists and clinicians are at a loss regarding the diagnosis, when the pathologist gets the section he may be puzzled too.

CASE 33142

PRESENTATION OF CASE

A forty-seven-year-old housewife entered the hospital because of a mass in the right axilla.

Three years before admission pain and weakness had developed in the right shoulder and axilla. A mass was discovered. The pain disappeared after a course of x-ray treatment. A year and a half later a second course of x-ray therapy was given because of the reappearance of pain. A few weeks before admission the mass was again present and somewhat painful. Three and two weeks prior to admission single doses of x-ray therapy were directed at the axilla. There was doubt whether irradiation altered the size of the mass.

No masses had ever been felt in the breasts, nor had there been pains in other parts of the body. No lymph-node enlargement had ever been noted. The system review and past history were noncontributory.

Physical examination showed a large, obese woman who weighed about 220 pounds and appeared in good health. In the right axilla there was a mass measuring 8 by 8 cm. that moved with the scapula. It felt firm but not stony hard, and was smooth and slightly tender. The overlying skin was not adherent, nor was the mass adherent to the chest wall. No lymphadenopathy was present.

The temperature, pulse and respirations were normal. The blood pressure was 190 systolic, 110 diastolic.

Examination of the blood revealed a hemoglobin of 13.6 gm per 100 cc and a white-cell count of 6200, with 53 per cent neutrophils. The urine gave a + test for albumin, and the sediment contained 25 red cells and 15 white cells per high-power field. The blood calcium was 8.9 mg, the phosphorus 2.2 mg, and the total protein 7.3 gm per 100 cc, and the phosphatase 3.0 Bodansky units. On x-ray examination the heart and lungs appeared normal. There was evidence of an old healed fracture of the distal third of the right clavicle. There was an oval soft-tissue mass in the medial wall of the right axilla, measuring approximately 11 by 6 cm. The outer wall was fairly well demarcated and smooth in outline. The upper two thirds of the lateral border of the scapula was irregular in outline.

An operation was performed on the eighth day.

DIFFERENTIAL DIAGNOSIS

Dr. GRANTLEY W. TAYLOR: The history is deplorably silent about whether the tumor disappeared after x-ray treatment. Perhaps we should see the x-ray films.

Dr. TOUFIC H. KALIL: The soft-tissue mass is best seen on this film. It measures 11 by 6 cm. and has a smooth, well defined outer border. The involved portion of the scapula is demonstrated by the irregular lateral margin produced by a small amount of bone destruction.

Dr. TAYLOR: In a discussion of the diagnosis of these lesions involving bone in the preceding case Dr. Simmons referred to the possibility of confusing inflammatory conditions and metabolic disturbances with bone tumors. It seems to me that we have nothing to suggest an inflammatory process or any generalized metabolic disturbance in this case. We are dealing with an axillary tumor, and there is little to go on except the tumor itself, the x-ray findings and the fact that the patient was apparently well in spite of the presence of tumor for over three years.

Was this a tumor of bone with soft-part extension, or tumor of the soft parts with erosion or irregularity of bone because of the propinquity of the process to the bone? I do not believe that one can say definitely. Dr. Kalil might like to make a statement regarding whether that amount of bone distortion could be due to impingement of a tumor on the soft parts.

Dr. KALIL: I should expect a smooth erosion rather than this type of irregularity in such a case.

Dr. TAYLOR: When we consider the bone tumors in this region we at once raise the question whether they are benign or malignant. In favor of a benign tumor in the case under discussion is the long course and the patient's excellent health in spite of the long course. We have one additional fact in the history that may be of some significance — namely, that x-ray treatments had been used, with adequate control of the symptomatology for some time. It would be helpful to know whether there was any change in the mass as a result of the previous irradiation. It is interesting that x-ray therapy relieves the pain in many conditions, in which it can almost be regarded as a type of physiotherapy. There seems to be something specific about the relief of pain by x-ray treatment in a large diversity of cases that are not necessarily neoplastic or malignant.

Dr. Kalil is unwilling to say that this amount of bone disease was due to the pressure of an adjacent tumor of the soft tissue. We must concentrate on bone tumors or tumors that may involve bone. Of the malignant tumors we must consider whether we are dealing with metastatic or primary tumors. This was a perfectly healthy person with nothing in the history to suggest metastases from any other part of the body. The one positive finding on laboratory examination was that the urinary sediment con-

DIFFERENTIAL DIAGNOSIS

DR CHANNING C SIMMONS In all these cases of bone lesions three main conditions should be borne in mind skeletal disease, an inflammatory condition and tumor, either primary or metastatic. Keeping these possibilities in mind, let us analyze this case. The patient was highly nervous, and complained of pain in the region of the coccyx. She had been operated on five months previously for pilonidal sinus. The pain was relieved by sigmoidoscopy. The x-ray films showed some trouble with the coccyx. Reading between the lines I believe that, at that time, a diagnosis was probably made of a low-grade infection, such as osteomyelitis, secondary to the pilonidal sinus. Why the pain was relieved by sigmoidoscopy, I do not know, that is not the ordinary treatment for either osteomyelitis or coccygalgia. I also do not know why nothing more was done after the findings showed a definite lesion of the coccyx.

May we see the first x-ray films?

DR TOUFIC H KALIL This is the soft-tissue mass referred to, and in the lateral view it can be seen extending down to replace the coccyx. The ragged appearance of the bone denotes destruction.

DR SIMMONS The patient was readmitted with a definite mass in that situation, and the pain continued. In this second series of films the mass appears larger than it was previously.

The one positive finding other than tumor is the high phosphatase in the blood. From the description of the x-ray examination there was bone destruction with new bone formation in the tumor, and the high phosphatase was probably due to new bone formation. We can rule out disease of the liver and kidney, in which the phosphatase may be high. The temperature was normal, the urine was normal. There is no evidence, so far as I can see, although we have no complete skeletal x-ray films, of generalized metabolic disease.

We have a definite possibility of an inflammatory condition. The patient had a pilonidal sinus, which is notoriously difficult to cure by operation, and there may have been a low-grade secondary infection persisting with involvement of the bone. Tuberculosis, I should think, can be ruled out. I have not seen anything suggesting that in the record or past history. The blood Hinton test was negative, that test, however, is sometimes negative with bone syphilis.

We then come down to some form of tumor, primary or metastatic. One primary tumor that does occur in this region is chordoma, which is frequently seen in the sacrum, although it may arise at the base of the skull, or any point in the spinal column. One should think of chondroma, Ewing sarcoma and ordinary osteogenic sarcoma, the last being relatively rare in this situation, however.

Metastatic tumors may have occurred from the rectum or cancer in any part of the body, although the patient was only nineteen, which is young for a primary carcinoma with metastases. This is not conclusive, however, because cancer does occur in the young. The only positive finding suggesting cancer is the mucus passed by rectum.

I do not see how one can rule out Ewing sarcoma.

I cannot make a diagnosis in this case. On the facts presented the most probable diagnosis is a chordoma, which is the most frequent tumor in this situation. I am probably wrong because this diagnosis seems so obvious and we know that all the cases that Dr Mallory puts up to us are problems. A chondroma is a second possibility, and the third is malignant lymphoma of some sort. I think that it is impossible to make a definite diagnosis without a biopsy.

CLINICAL DIAGNOSIS

Tumor of sacrum and coccyx, unspecified

DR SIMMONS'S DIAGNOSIS

Chordoma?

ANATOMICAL DIAGNOSIS

Benign giant-cell tumor of coccyx and sacrum

PATHOLOGICAL DISCUSSION

DR TRACY B MALLORY The opinion on the ward was the same as Dr Simmons's that it was impossible to make a diagnosis without a biopsy. The patient was operated on, and a segment of the tumor removed. I believe that while we were attempting to make a frozen section, the surgeon went ahead with the resection of the lower portion of the sacrum and the coccyx. The tumor proved rather puzzling on frozen section, as such lesions often do. It consisted of a considerable amount of fibrous tissue in which there were spicules of osteoid and a large number of foreign-body giant cells. On the basis of the general appearance I thought that benign giant-cell tumor was the most probable diagnosis. When the better sections came through, we were in somewhat the same predicament as Dr Simmons. The picture varied from one area to another, the tumor was much more fibrous and had a good deal more bone formation than is usual with a benign giant-cell tumor. The picture in some places suggested a condition that we call fibrous dysplasia of bone. In other areas large foreign-body giant cells were numerous. We made a final diagnosis of benign giant-cell tumor, although the possibility that it should be classed as fibrous dysplasia still exists. I can remember one other case of benign giant-cell tumor of the spinal column that extended out into the soft parts and eventually spontaneously broke through the skin of the back. The diagnosis was made by biopsy, and following x-ray therapy the lesion disappeared almost miraculously fast. and

Addendum to Case 33041 * A sixty-nine-year-old farmer, previously treated for a chondroma of the popliteal space by excisional surgery, was readmitted to the hospital two weeks after discharge. He complained of severe pain and stiffness in the right knee that had steadily increased since operation.

To determine whether the pain and limitation of motion were bona fide and to estimate the range of motion of the knee joint when the factor of pain was eliminated, a manipulation was done under Pentothal anesthesia. The range of motion of the knee was from 90 to 170°—with an average of 80°—and was all that could be obtained without force.

After the manipulation, the patient complained that the knee was more painful than ever, and he held the knee at 150° and resisted motion in both directions. The x-ray films at that time showed a recurrence of the tumor. There were multiple areas of calcification in the posterior aspect of the joint. The patient became anxious and worried about "cancer" when he was advised that only amputation would relieve the pain and cure the tumor. He was sent home to think the matter over more thoroughly and to calm his fears.

He returned to the hospital for a third admission, eight weeks after the previous operation. He asked that the leg be amputated because the pain was even severer than previously and there was no motion in the knee joint, which he held at 115°. He objected to any attempt at passive motion. There was palpable induration of the joint capsule. The entire knee was acutely painful to palpation, especially over the joint line on both the medial and the lateral aspects.

Under nitrous oxide, oxygen and ether anesthesia, a mid thigh amputation was done nine weeks after the previous operation in which the original tumor had been removed from the popliteal space. Pathological study of the specimen showed a complete knee amputation sharply 10 cm. above the joint and 16 cm. below, with overlying muscle, soft tissues and skin. Posterior to the knee joint there was a firm cartilaginous, somewhat nodular, tumor mass measuring 6.5 by 5 cm. and extending posteriorly for 3 cm. Although the mass was firmly adherent to the head of the tibia, no direct connection of the growth was found, and it was likewise separated a few millimeters from the femoral head. The synovial wall was involved, a few small seedings were noted on the articular surface of the tibia and in the anterior synovial membrane, and even over the tip of the patella there was a 4-mm. seed (Fig. 1). The

popliteal artery and vein were free of involvement. Section through the tumor proper revealed a fairly homogeneous cartilage, with a few small, soft, brown areas and foci of hemorrhage. The surface of the

FIGURE 1

tumor was smooth but without a definite capsule. There was a small amount of red marrow on the head of the tibia, but otherwise it was fatty.

The tumor was composed of many large and small separate islands of well differentiated cartilage, with few cells and abundant hyaline matrix. Nearly all the islands were surrounded by narrow borders of myxomatous tissue that in places showed suggestive patterns of transition into cartilage. It was not possible to be certain whether this myxomatous tissue represented part of the neoplasm or a metaplastic process in the surrounding synovia. Although the usual histologic features of cancer were largely lacking, the infiltrative character and the rapid recurrence justified a diagnosis of chondrosarcoma.

The patient was discharged with an artificial limb. The stump was painless and functioned well.

S. L. J. Med. 236:145-148, 1947.

tained 25 red cells and 15 white cells per high-power field. There was some albumin. I assume that that may not have been a catheterized specimen, because no attention seems to have been paid to it. If it had been a catheterized specimen, it seems to me that one would have to investigate further, at least to the extent of a pyelogram or some other investigation of the genitourinary tract.

Could this have been a metastasis from a primary neoplasm of the genitourinary tract? It had been present for three years. In that time the patient should have had symptoms referable to the kidneys or bladder. I therefore think that we must concentrate on the notion that this was a primary tumor. The results of x-ray treatment in the past argue a little more in behalf of a malignant than of a benign tumor, but the long course and the excellent health are more in favor of benign than malignant tumor. We can bet our money and take our choice. The fibromas, fibrosarcomas and periosteal fibrosarcomas seem to share the properties of soft parts and bone, and give rise to considerable soft-part tumors with less extensive bone involvement than occurs with osteogenic sarcoma or Ewing tumor or some of the other primary bone tumors. Chondromas and chondrosarcomas are likely to show evidence of bone formation or calcification within the tumor and to be lobular on palpation and on x-ray study of the soft-tissue swelling. We have had a certain number of synoviomias, but they are usually highly malignant, and rapidly growing. They may occur in this region not immediately in a joint but more or less removed from the joints and skeletal structure. Some of the ones we have seen here have given some indication of calcification. I do not see any evidence of calcification in this tumor.

Finally, we come to the group of lymphoblastic tumors that may involve bone and present soft-tissue tumors that respond gratifyingly to x-ray therapy. It is interesting that on physical examination no reference was made to the character of the skin in the axilla after two courses of x-ray therapy. It seems that that point might be relevant, because it would give some indication of the amount of x-ray treatment that had been given to relieve symptoms and perhaps to make the tumor disappear.

There are other rarer tumors that we can allude to simply for the sake of completeness, but I do not believe that we can make a diagnosis. We are confronted with a mass that involved the bone, and we shall have to resort to immediate pathological examination, the decision regarding the character of the tumor depends on the result of such examination. I favor a periosteal fibrosarcoma as a likely diagnosis, but it is anybody's guess.

DR NORMAN J. WILSON: I might add that this woman insisted that the tumor in her opinion had decreased with each course of x-ray therapy except the last, which had been inadequate. She had

definite relief of pain. Just how much the tumor decreased we could not tell because we had only the patient's word for it. It did not disappear entirely, however, because she was always able to feel it and was conscious of its presence.

DR TAYLOR: That should help me, but it does not.

DR TRACY B. MALLORY: Will you describe the operation, Dr. Wilson?

DR WILSON: We biopsied this tumor preoperatively and waited for the report before proceeding with treatment. We had considerable difficulty getting at the tumor. On the first attempt, we found a well encapsulated structure and took three good pieces of tissue from what we thought was tumor but discovered to be nothing but muscle overlying the tumor, the muscle had evidently been heaped up there as a result of reaction around the tumor and of the x-ray treatment. We were forced to make a larger incision and even then had considerable difficulty in getting a satisfactory biopsy. Dr. McKittrick resected the scapula below the spine along with the tumor en masse. At operation, when we approached the tumor we could not determine whether it was attached to the scapula anywhere, and the scapula to all intents and purposes was normal.

CLINICAL DIAGNOSIS

Fibrosarcoma of axilla?

DR TAYLOR'S DIAGNOSIS

Periosteal fibrosarcoma

ANATOMICAL DIAGNOSIS

Fibromyxosarcoma

PATHOLOGICAL DISCUSSION

DR MALLORY: The biopsy that was finally taken on this patient showed a neoplasm that we described as a fibromyxoma. After the resection and further sections we qualified that slightly and decided to call it a slowly growing fibromyxosarcoma. It was on the borderline of malignancy and well circumscribed but not completely encapsulated. Since we were unable to make out any point of true attachment to the scapula or its periosteum we thought that it was a tumor of the soft parts, with secondary erosion of the scapula, which is the other possibility that Dr. Taylor mentioned.

DR TAYLOR: I should have said — and meant to say — that, having argued against neoplastic disease on the grounds that this patient was in excellent health, I finally made a diagnosis of a type of malignant process that is frequently slowly growing in its propensity to spread and does not impair the patient's general condition for a long while — namely, a periosteal fibrosarcoma.

suggests that medical students should receive training in sex relations, on the basis of the average physician's inadequate equipment in this field, and undoubtedly he is right. At least the student would be made to realize the importance of the subject, and that it is in his province if he really wishes to make of himself the wise counselor that he should be. One difficulty, however, is that scientific knowledge is increasing by leaps and bounds, that the medical curriculum is already overloaded and that each department chronically needs more time in which to deliver its fundamental message.

Perhaps the curriculum of the average school is not now well planned, undoubtedly there is too much obstetrics for the future ophthalmologist, too much orthopedics for the embryonic laryngologist, too much surgery for the potential psychiatrist. The medical school, after all, can turn out only a doctor of medicine, not a physician or a surgeon, a dermatologist, an allergist or a pediatrician. The duty of the school, as it sees itself, is to impart basic principles and to give the student at least a speaking acquaintance with the various specialties of medicine and surgery. The medical school does not so much take the student onto a high place and point out the promised lands spread before him as it takes him into a broad valley from which he can see the peaks that challenge him to climb. The graduate himself, by his own efforts, having seen the range spread out in panorama before him, must essay the trail that will take him to his chosen peak.

Dr. Oliver Wendell Holmes, just seventy-five years ago last March, delivered a valedictory address to the graduating class of Bellevue Hospital College. His title was "The Young Practitioner," and his thesis, the theory — not altogether new — that the young graduate, bursting with knowledge, was not really a physician until he had gone through a depleting process to get rid of his extra medical-school learning and had replaced it with the fruits of experience. "Hard work," counseled the Autocrat, "will train it off, as sharp exercise trains off the fat of a prize-fighter." And again, from the same source, "Knowledge that is not wanted dies out like the eyes of the fishes of the Mammoth Cave."

Some knowledge of sex-counseling should undoubtedly be imparted to each candidate for the medical degree, even for his own sake, just as he is

required to have at least a smattering of ignorance on the mechanics of the birth of twins. Nothing, however, will make the student a good physician in this or in other matters unless he wishes to transmute his information into the right type of wisdom. "If you ship a poor cask of wine to India and back," said Dr. Holmes in 1871, "if you keep it half a century, it only grows thinner and sharper."

NEW ENGLAND DIABETES ASSOCIATION

ALTHOUGH insulin has been in use for over twenty-five years, the number of deaths attributed to diabetes continues to increase, and the disease ranks eighth among the leading causes of death in the United States. The New England Diabetes Association, a notice of whose organization meeting on April 16 appears elsewhere in this issue of the *Journal*, is an outgrowth of occasional informal gatherings held, for several years before the outbreak of World War II, by a group of physicians interested in the growing problem of diabetes as a disease affecting a sufficient proportion of the population to be considered a matter of concern to the community at large.

The purpose of the new association is to afford physicians, dietitians, nurses and other scientific workers especially interested in the welfare of diabetic patients an opportunity to meet regularly for discussion of the manifold problems of the diabetic patients in New England, conservatively estimated to number 80,000. Similar organizations have been of great value in the treatment of heart disease, tuberculosis, cancer and the arthritides. The formation of the New England Diabetes Association occurs at a time when the United States Public Health Service, with which it has no direct connection, is displaying an active interest in diabetes as a public-health matter. Physicians generally and specialists in diabetes in particular will welcome the efforts of the new organization.

MASSACHUSETTS MEDICAL SOCIETY BUREAU OF CLINICAL INFORMATION

All secretaries of various medical groups, such as special societies and alumni associations, are requested to notify the Bureau of Clinical Information regarding scheduled meetings, annual dinners and so forth. If such data are on file, it is hoped that duplication of dates can be avoided.

PUBLIC-HEALTH SERVICES IN MASSACHUSETTS

THE shortage in trained professional workers has created a critical situation in the Massachusetts Department of Public Health and Department of Mental Health and in many municipal health departments in the Commonwealth. At the present time these departments are operating under the handicap of a greatly reduced personnel, including physicians, nurses and other workers. For instance, in the Department of Public Health about 50 per cent of the positions filled by physicians and 40 per cent of those occupied by hospital workers are now vacant. Unless remedial steps are soon taken, the vital health services of these departments will be seriously impaired.

The shortage of physicians has been brought about, to a large extent, by the existing low-salary levels. The present scale of salaries of physicians in the service of the Commonwealth is considerably below those of the federal government and of many states. In fact, Massachusetts ranks thirty-eighth among the states in the average salary levels of public-health physicians. As a result there has been a continuous loss of capable men, attracted elsewhere by more lucrative positions in the federal and state services or in general practice, and a corresponding inability to fill these vacancies with well trained men, since inadequate salaries preclude competition with other agencies.

At its February meeting, the Council of the Massachusetts Medical Society, recognizing the gravity of the situation, voted to instruct the Committee on Legislation to give its support to an active program for raising the salary levels of physicians and other professional workers in the services of the Commonwealth or one of its political subdivisions. The Society considers that the scale of salaries in these state and local departments should be placed at levels that will allow Massachusetts to compete with outside agencies for the services of properly trained persons. In brief, the establishment of salaries on a competitive level appears to be the most logical and practical step for correcting the present unfortunate situation.

" TO GROW IN WISDOM "

THE part that the doctor should play in marriage counseling and in sex instruction was the subject of a talk given recently before the Planned Parenthood League of Massachusetts by Dr. James C. Janney, president of the Marriage Study Association. Dr. Janney's belief that many marriages are wrecked because of a lack of understanding and of good judgment in sex matters will be accepted by anyone who has given the subject any thought, and it must be equally apparent that the physician should be the one best equipped to give advice on the subject.

How the physician should acquire such knowledge, however, and how he can be interested in accepting what is clearly a professional obligation are difficult questions to answer directly. Dr. Janney

BOOK REVIEWS

Hazzell's Textbook of Physiology. Edited by John F. Fulton, M.D., Sterling Professor of Physiology, Yale University School of Medicine. Fifteenth edition 8°, cloth, 1304 pp., with 507 illustrations. London W. B. Saunders Company, 1946 \$8.00

It is a point of much importance that the distinguished Sterling Professor of Physiology at Yale University School of Medicine has undertaken to edit the fifteenth edition of this work, which has been a pacemaker of the subject in this country since its first appearance in 1905. This book, in which functional mechanisms are constantly brought into sharp focus, will be welcomed alike by students and physicians.

The ten sections of the volume include contributions by eminent authorities in their respected fields. Initially, the reader is presented with a brief, concise and thoroughly interesting chapter "Historical Backgrounds of American Physiology" by Dr. Fulton. The titles and the authors of the other sections are as follows: "Principles of Nervous and Muscular Activity," by David P. C. Lloyd; "The Central Nervous System Motor functions," by John F. Fulton; "The Nervous System Sensory functions," by Theodore Roch; "Properties and Constituents of the Blood," by David I. Hitchcock; "Physiology of the Organs of Circulation of the Blood and Lymph," by Donald H. Barron; Harold Lampert and John F. Fulton, "Respiration," by Leslie F. Nims; "Body Fluids and Kidney," by Robert W. Clarke; "Physiology of Digestion and Secretion of the Alimentary Tract," by George R. Cowgill; "Metabolism and Nutrition," by John R. Brobeck; and "Physiology of Reproduction," by William U. Gardner.

This book contains fifty-six chapters. At the end of each chapter there are a number of excellent references. The editor and his collaborators have presented their material in a clear style, offering the complexity of detail and the fluidity of ideas that characterize present-day physiology in a manner that leaves little room for criticism of the authors for the omission of this or that particular subject matter. This book is a refreshing product at the hands of critical scholars and is sure to be of real service to all who study it.

The Bacterial Cell In its relation to problems of virulence, immunity and chemotherapy. By René J. Dubos. With an addendum by C. F. Robinow. 8°, cloth, 460 pp., illustrated. Cambridge, Massachusetts Harvard University Press, 1945 \$5.00

This book, a Harvard University Monograph in Medicine and Public Health, is a thoroughly documented expansion of a series of eight lectures delivered in 1944 at the invitation of the Lovell Institute in Boston. The Institute, managed

by a single trustee, has long deserved an enviable reputation for its wise and happy choice of lecturers. In selecting Dr. Dubos at that time George Fabyan Professor of Comparative Pathology and professor of tropical medicine, Schools of Medicine and Public Health, Harvard University, and also a member of the Rockefeller Institute, the high requirements have been fully met — thorough familiarity with the field of knowledge, demonstrated ability in original basic research, and a capacity for lucid exposition. An illustration of the author's philosophic temper is his choice of the quotations that head chapters and sections. In source, these "texts" range from St. Paul's "Epistle to the Corinthians" to Lewis Carroll and include aphoristic selections from Bacon, Bernard, Cohn, Ehrlich, von Liebig, Pasteur, Renan, Rousseau and Shelley.

The first chapters deal with the complexity of bacterial cells as revealed by direct cytologic examination and reaction to stains. Capsules, flagella, granules, nuclear structures, spores, cell division and colonial characteristics are discussed, with particular attention to their relation to pathogenicity. Revelations provided by electron micrographs are elaborated in the addendum by C. F. Robinow, of Cambridge, England.

Enzymic reactions contribute something to knowledge of bacterial structures. The nature, number and sometimes the architectural location of bacterial antigens have been profitably studied via the action of bacteriophages and the application of serological analysis, especially in connection with pneumococci and *Salmonella*.

Bacterial variations are considered, on admittedly inadequate evidence, to be probably ascribable to some selective process operating on forms originally present in the parental culture. Concerning the transformation of pneumococcal types, however, it appears that a real genetic mutation is induced by a highly polymerized deoxyribonucleic acid. If the strong evidence upholding this concept turns out to be valid, its discoverers (Avery, MacLeod and McCarty) have made a fundamental contribution that is likely to have wide and profound scientific applications.

The illuminating discussion of virulence and its intricate nature, in terms of modern concepts, is not equaled in any publication that the reviewer has seen. The importance of the host is considered, but Dubos's analysis of infection deals more with antigenic structure, toxins, variations and adaptations. Recognition that virulence is a complex quality and that modification or loss of only one of its components (each readily capable of independent variation) may abolish pathogenicity has the effect of multiplying the points of vulnerability of harmful micro-organisms, thus in turn affords a correspondingly increased number of mechanisms with which antibiotic agents may effectively interfere. In the discussion of immunization against infections and in nearly sixty pages given over to bacteriostatic and bactericidal agents this conception is expanded in relation to the multiplicity of immunochemical structures and specificities of cellular components, as well as the intimate nature of such metabolic processes as nutrition, respiration, growth and division.

Most studies of antibiosis have emphasized the effect of various agents on catabolic reactions, but there are a few cases in which it seems that the essential primary effect of the inhibition is on a synthetic anabolic process vitally necessary to bacterial activities. Wider and more detailed studies of bacterial physiology and nutrition are highly desirable, that chemotherapy may advance more logically and rapidly. The mechanisms of drug-fastness receive detailed consideration. The final chapter on trends and perspectives deals chiefly with the nature of specificity and the significance of bacterial variability.

The bibliography comprises about a thousand titles, the text page on which the citation is discussed is also indicated — an especially helpful feature that should be widely copied. Type and presswork are excellent.

Least all these comments be deemed too uniformly fulsome, the reviewer protests against the use of "haptene." This spelling is probably a mere upshoot from the author's Gallic origin, but it is a retrogressive step toward "toxine," "agglutinine" and so forth, current within the reviewer's memory, and it is an unwarranted meddling with Landsteiner's neologism "haptene."

This is an important book — crucial, penetrating, informative stimulating and, especially, heuristic. Despite the existing primitive and fragmentary knowledge or complete

DEATHS

DOLE — Mary P. Dole, M.D., of Shelburne, died February 23. She was in her eighty-fifth year.
Dr. Dole received her degree from Woman's Medical College of Baltimore in 1888.
Several nieces and nephews survive.

GIGGER — Augustus G. Gigger, M.D., of Falmouth, died November 27. He was in his sixty-ninth year.
Dr. Gigger received his degree from Boston University School of Medicine in 1906.

JENNINGS — John G. Jennings, M.D., of Weston, died February 17. He was in his fifty-ninth year.
Dr. Jennings received his degree from Tufts College Medical School in 1915. He was a member of the staff of the Massachusetts Eye and Ear Infirmary and of the Waltham Hospital, as well as a member of the New England Ophthalmological Society and a fellow of the American Medical Association.
His widow, a daughter and a son survive.

KEES — Philip A. Kees, M.D., of West Springfield, died November 4. He was in his thirty-ninth year.
Dr. Kees received his degree from University of Minnesota Medical School in 1936. He served as a medical officer in World War II, receiving the Purple Heart, The Bronze Star for valor and the Silver Star for gallantry in action. He was a fellow of the American Medical Association.
His widow and three children survive.

SEDGLEY — Frank R. Sedgley, M.D., of Redwood City, California, died February 12. He was in his sixty-eighth year.
Dr. Sedgley received his degree from Boston University School of Medicine in 1902. He was a fellow of the American College of Surgeons and the American Medical Association.
His widow survives.

SMITH — Roswell H. Smith, M.D., of Edgartown, died February 12. He was in his fifty-third year.
Dr. Smith received his degree from Middlesex University School of Medicine in 1922.
His widow and two daughters survive.

TYNAN — Joseph P. Tynan, M.D., of South Boston, died recently. He was in his sixty-third year.
Dr. Tynan received his degree from Tufts College Medical School in 1910.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

SHORTAGE OF CONTAINERS FOR BIOLOGIC PRODUCTS

The shortage of containers for serum, vaccines and blood products is at present more critical than ever, and deliveries of new supplies cannot be expected in less than five or six months. A further complication arises from the great increase in the demand for biologic products. During the past six months distribution of certain products has increased, as against one year ago, to the following extent: diphtheria antitoxin, 94 per cent, diphtheria toxoid, 160 per cent, Schick outfits, 159 per cent, typhoid vaccine, 47 per cent, and immune serum globulin, 303 per cent. Distribution of plasma begun in March, 1946, has totaled 16,748 units, and 4458 pints of whole blood have been issued since May, 1946, when this service was begun.

The Department of Public Health cannot maintain the present rate of distribution unless empty containers or unused products of all types are re-

turned. Blood bottles in particular represent a considerable expense to the Commonwealth, and their prompt return is essential if this service is to be continued. Physicians, hospitals and health agencies are most urgently asked to co-operate with the Department in the present emergency, as they did so outstandingly during the war, by returning as many containers as possible, either to local board-of-health depots, to district health offices or directly to the Division of Biologic Laboratories. When other transportation cannot be arranged, large shipments may be sent express collect to the Division of Biologic Laboratories, 375 South Street, Jamaica Plain. For detailed arrangements or information telephone ARNold 4127.

COMMUNICABLE DISEASES IN MASSACHUSETTS FOR JANUARY, 1947

DISEASES	RÉSUMÉ		
	JANUARY 1947	JANUARY 1946	SEVEN YEAR MEDIAN
Chancroid	1	3	3*
Chicken pox	2,391	1,023	1,798
Diphtheria	77	10	14
Dog bite	522	487	511
Dysentery, bacillary	10	4	6
German measles	108	73	130
Gonorrhea	360	663	357
Granuloma inguinale	1	0	0*
Lymphogranuloma venereum	1	1	1*
Malaria	7	52	1018
Measles	1,885	1,018	18
Meningitis meningococcal	9	24	18
Meningitis Pfeiffer-bacillus	3	3	7†
Meningitis pneumococcal	1	7	0†
Meningitis, staphylococcal	0	0	0†
Meningitis, streptococcal	0	1	2†
Meningitis, other forms	1	3	5†
Meningitis, undetermined	4	4	913
Mumps	666	698	390
Pneumonia, lobar	142	325	2
Poliomyelitis	5	0	5

Typhoid fever	3	1	2
Undulant fever	3		
Whooping cough	895	480	625

*Three-year median

†Five-year median

COMMENT

Interest in communicable diseases continues to focus on the increased prevalence of diphtheria. The number of cases reported in January is nearly eight times the number in the same month in 1946, and more than five times the seven-year median. Boston and New Bedford, which have had an increased prevalence during the last three years, continued to report the bulk of the cases. The disease appears, however, to be spreading into the Connecticut Valley, and an upward trend can be expected in that area unless immunization procedures are redoubled.

Other diseases above the seven-year median for the month were chicken pox, bacillary dysentery, measles, poliomyelitis, salmonellosis, pulmonary tuberculosis and whooping cough.

Among the diseases below the seven-year median were meningococcal meningitis, mumps, lobar pneumonia and scarlet fever.

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Diphtheria was reported from Boston, 30, Brookline, 1, Cambridge, 1, Chelsea, 8, Clinton, 1, Everett, 2, Fall River, 1, Greenfield, 2, Holyoke, 1, Ipswich, 1, Lowell, 3, Lynn, 2, New Bedford, 12, Palmer, 2, Randolph, 1, Somerville, 4, Springfield, 2, Stoughton, 1, Wayland, 1, West Bridgewater, 1, total, 77.

Dysentery, amebic, was reported from Boston, 1, total, 1.
Dysentery, bacillary, was reported from Salem, 1, Worcester, 5, Wrentham, 4, total, 10.

Number 15

THE USE OF CURARE IN ANESTHESIA*

EDWARD C. ALLEN, M.D.,† AND URBAN H. EVERSOLE, M.D.‡

BOSTON

FOR the past few centuries, curare has been dismissed lightly as being synonymous with the generic name of several arrow poisons of certain South American Indians, but investigation of its pharmacologic action and clinical application in the past decade has shown this drug to hold great promise to the anesthesiologist. The first descriptions of this so-called "arrow poison" were brought back to the civilized world by Sir Walter Raleigh in 1595 following his journey to Guiana and up the Orinoco.¹ Because of the variable source and potency of the drug and because of the toxic effects due to the impurities in the crude preparations, little advance was made in its investigation until the researches of the eminent physiologist Claude Bernard on its use in hydrophobia, chorea, tetanus and epilepsy. From his work came the first realization that the physiologic action of curare takes place at the myoneural junction.

Full credit for the modern development of curare must be given to Gill,¹ who spent much time in the Amazonian jungles and in 1938 brought back to this country adequate supplies of the drug for investigative work. From that time on there has been no standstill in research on the properties of this drug. Gill² recently cleared up what he considered misconceptions about the source and development of the drug. He stated that curare is not derived from a single species of plants but is a mixture of botanical components, widely distributed throughout northern and western South America, more particularly in regions of Amazonian drainage. The type of primitive container, whether it is a bamboo tube or gourd, bears no relation to the type of curare it contains.

McIntyre³ and Bennett,^{4, 5} at the University of Nebraska, conducted the first modern pharmacologic study and clinical trial of the drug. It was first used in the field of psychiatry in an attempt to overcome some of the less desirable accompaniments of convulsive shock therapy. To Griffith

and Johnson,⁶ of Montreal, goes the credit for the introduction of curare to the field of anesthesiology in 1942. They reported the effectiveness of this drug in producing muscular relaxation in patients anesthetized with cyclopropane. Numerous reports of the successful use of curare to enhance muscular relaxation in conjunction with all types of general anesthetics were subsequently made.⁷⁻¹⁵

Intocostin§ — a standardized product of greater purity — has been available since 1940. It is a clear, amber-colored solution supplied in rubber-stoppered vials containing 20 mg. of the crude drug per cubic centimeter. It is biologically assayed and tested in man before being distributed. It is sufficiently free of hydrolyzable resins so that it is not subject to clouding for at least a year if kept refrigerated. Little has been mentioned in the literature concerning its chemical nature, although it has been said to resemble bisbenzylisoquinoline alkaloid.¹⁶ It is best administered intravenously but can be given intramuscularly, allowance for the time interval for effective action being made. Intocostin is nonirritating to tissues even when given subcutaneously.

The primary site of physiologic action of curare is peripherally at the myoneural junction. The exact nature of this mechanism is not completely understood. The muscle response to the acetylcholine influence at the myoneural junction is markedly diminished either by an increase in the threshold of reaction to the normal concentration of acetylcholine or by a sort of neutralization of the acetylcholine activity. Regardless of the mechanism, the result of administration is a paresis or paralysis of the voluntary musculature throughout the body. There is a progressive action on muscle groups starting with the head and neck and extending downward to the trunk and extremities and lastly to the muscles of respiration. Fortunately, the diaphragm is the last muscle to be affected. There seems to be a paresis first in the short muscles of the head supplied by cranial nerves and then the longer muscles of the neck, trunk and extremities.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Renal Hypertension By Eduardo Braun-Menéndez, Juan Carlos Fasciolo, Luis F. Leloir, Juan M. Mumoz and Alberto C. Taquini, Institute of Physiology, Faculty of Medical Sciences, and Institute of Cardiology, V. F. Grego Foundation, Buenos Aires, Argentina. Translated by Louis Dexter, M.D. Harvard Medical School and Peter Bent Brigham Hospital. 8°, cloth, 451 pp., with 90 illustrations. Springfield, Illinois: Charles C. Thomas, 1946. \$6.75.

Ambulatory Proctology By Alfred J. Cantor, M.D., associate proctologist, Kew Gardens General Hospital, Long Island, New York. With a foreword by Beaumont S. Cornell, M.D., editor, *American Journal of Digestive Diseases*. 8°, cloth, 524 pp., with 281 illustrations. New York and London: Paul B. Hoeber, Incorporated, 1946. \$8.00.

Handbook of Neurological Examination and Case Recording By D. Denny-Brown, M.D., James Jackson Putnam Professor of Neurology, Harvard Medical School. 12°, paper, 112 pp. Cambridge, Massachusetts: Harvard University Press, 1946. \$1.75.

Penicillin: Its practical application Under the general editorship of Sir Alexander Fleming, M.D., B.S., F.R.C.P., F.R.C.S., F.R.S., professor of bacteriology in the University of London, St. Mary's Hospital, London. 8°, cloth, 380 pp., with 59 illustrations. Philadelphia: Blakiston Company, 1946. \$7.00.

Introduction to Surgery By Virginia Kneeland Frantz, M.D., assistant professor of surgery, Columbia University College of Physicians and Surgeons, associate attending surgical pathologist, Presbyterian Hospital, New York City, and Harold Dornic Harvey, M.D., assistant professor of clinical surgery, Columbia University College of Physicians and Surgeons, assistant attending surgeon, Presbyterian Hospital, New York City. 12°, cloth, 216 pp. New York: Oxford University Press, 1946. \$2.50.

Myasthenia Gravis By Dr. Adalberto R. Goni, member of the staff of the Hospital Alvear, Buenos Aires, chief, Medical Clinic of the Sanitary Service of the Post Office, Telephone and Telegraph. Translated by Georgianna Simmons Gittinger. 8°, cloth, 112 pp., with 10 illustrations. Baltimore: Williams and Wilkins Company, 1946. No charge.

Lippincott's Quick Reference Book for Medicine and Surgery: A clinical, diagnostic and therapeutic digest of general medicine, surgery and the specialties, compiled systematically from modern literature By George E. Rehberger, M.D. Thirteenth edition. 4°, cloth, 1461 pp., with 302 illustrations. Philadelphia: J. B. Lippincott Company, 1946. \$15.00.

Western Reserve University Centennial History of the School of Medicine By Frederick C. Waite, A.M., Ph.D. 8°, cloth, 588 pp., with 15 illustrations and frontispiece. Cleveland: Western Reserve University Press, 1946. \$6.00.

NOTICES

JOSEPH H. PRATT
DIAGNOSTIC HOSPITAL

Bennet Street, Boston
Lecture Hall, 9-10 a.m.
MEDICAL CONFERENCE PROGRAM

Wednesday, April 9 — Functional Tests in the Diagnosis of Pancreatic Disease. Dr. Martin Nothmann.

Friday, April 11 — Di-isopropyl Fluorophosphate in its Control of Glaucoma. Dr. Edwin B. Dunphy.

Wednesday, April 16 — Clinicopathological Conference. Drs. Robert Williams and H. E. MacMahon.

Friday, April 18 — Studies in Histochemistry. Dr. Henry Bunting.

Wednesday, April 23 — Pediatric Clinicopathological Conference. Drs. James M. Baty and H. E. MacMahon.

Friday, April 25 — Temporal Arteritis. Dr. Roy C. Crosby.

Wednesday, April 30 — The Relation of Enzyme Chemistry to Some Recent Advances in Chemotherapy. Dr. Gerhardt Schmidt.

On Tuesday and Thursday mornings, Dr. S. J. Thannhauser will give medical clinics on hospital cases. On

Saturday mornings, clinics will be given by Dr. William Dameshek. Medical rounds are conducted each weekday by members of the staff from 12:00 to 1:00 in the Lecture Hall. All exercises are open to the medical profession.

NEW ENGLAND DIABETES ASSOCIATION

The first meeting of the New England Diabetes Association will be held on Wednesday, April 16, at 7:30 p.m., in the Dowling Amphitheater, Boston City Hospital.

PROGRAM

Diabetes and Hyperthyroidism. Drs. Frank N. Allan and Rosemary Murphy.

The Relation between Insulin Sensitivity and Insulin Resistance. Dr. Francis C. Lowell.

Diabetic Coma at the Boston City Hospital. Dr. W. R. Ohler.

Renal Disease in Diabetes. Dr. Stanley Robbins.

A brief business meeting for the purpose of electing officers and directors and adopting a constitution, will follow.

Physicians, surgeons, nurses, dietitians and other scientific workers interested in the problems of diabetes may apply for membership at the meeting or may write for application blanks to the temporary secretary, Dr. James H. Townsend, 330 Mt. Auburn Street, Cambridge.

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING THURSDAY, APRIL 10

FRIDAY, APRIL 11

*9:00-10:00 a.m. Di-isopropyl Fluorophosphate in its Control of Glaucoma. Dr. Edwin B. Dunphy. Joseph H. Pratt Diagnostic Hospital.

*10:00 a.m.-12:00 m. Medical Staff Rounds. Peter Bent Brigham Hospital.

12:00 m.-1:00 p.m. Clinicopathological Conference (Boston Floating Hospital). Joseph H. Pratt Diagnostic Hospital.

MONDAY, APRIL 14

*12:15-1:15 p.m. Clinicopathological Conference. Peter Bent Brigham Hospital.

TUESDAY, APRIL 15

12:00 m.-1:00 p.m. Dermatological Service, Grand Rounds. Amphitheater, Dowling Building. Boston City Hospital.

*12:15-1:15 p.m. Clinicoradiological Conference. Peter Bent Brigham Hospital.

(Notices continued on page xvii)

tory in some cases in which actual laryngeal spasm occurs as a result of inadequate general anesthesia used coincidentally with the injection of curare Knight,²⁴ on the other hand, has found curare to be practically specific in cases in which laryngeal spasm develops during anesthesia. This point is still quite controversial.

In patients in whom shock is present or appears imminent, and in elderly or debilitated patients, it is wise to use smaller doses than are ordinarily employed.

Cyclopropane appears to be the ideal anesthetic agent to be used in combination with curare. The patient is carried in a light plane (usually the second) of anesthesia throughout. Curare neither increases nor decreases the irritability of the heart when employed with cyclopropane. This combination affords a pleasant and rapid induction and recovery with no aftereffects, and its most ardent supporters believe that the relaxation compares favorably with that obtained with spinal anesthesia.

Curare has been used with both the weaker gases nitrous oxide and ethylene.²⁵ Neither of these alone is capable of causing good flaccid muscular relaxation, and yet the relaxation from its combination with curare is satisfactory for upper abdominal operations. Much larger doses of curare are employed with these gases than with the more potent anesthetic agents, and in some cases there has been marked respiratory depression.

When curare is used to supplement ether anesthesia, great precaution must be taken in its administration. Ether has been demonstrated to have an action similar to that of curare, so that the myoneural junction is already partially paralyzed. There is a sort of cumulative action so that all the effects of curare will be increased, especially the length of respiratory depression. Thus, it is advisable to use smaller doses of curare, either 20 or 40 mg, instead of the usual 60 mg. Several cases of severe circulatory depression after the combination of ether and curare have been reported. Cullen²⁶ stated that this curariform action is an attribute not only of ether but also of tribromethanol and Pentothal Sodium, especially when the blood concentration is high.

The recent literature contains favorable reports on the combined use of curare and Pentothal,²⁷ but again a word of warning is necessary. It must be remembered that with this combination two respiratory depressants are being used at the same time. Provided that the anesthetist is fully capable of dealing with any respiratory problem that may arise, — whether it is depression or obstruction, — there is no great danger in the combination. Pentothal and curare should not be given through the same needle because of the formation of a precipitate. Recent development of a crystalline product is reported to overcome this disadvantage. Experience has shown that the total dose of Pentothal

is definitely reduced when the drug is used in conjunction with curare and also that the period of postoperative narcosis is considerably shortened.

There are a few definite contraindications to the use of curare. It should not be administered when myasthenia gravis is present or when there exists the least possibility that the anesthetist will be unable to deal with the problem of artificial respiration. It probably should not be used in patients with suspected liver or renal impairment.

Although prostigmine is the direct antidote for curare, there have been no reports of its use even in cases in which large doses of curare were given and periods of apnea resulted. Treatment has consisted solely of artificial respiration.

Curare has proved to be a valuable adjunct to spinal anesthesia. This is true when a single-dose agent has produced anesthesia of insufficient duration for the completion of the operation. The total amount of spinal-anesthetic agent needed when the continuous technic is employed is often materially lessened by the administration of curare toward the end of the operation. This may be significant in view of the fact that there is considerable evidence that neurologic complications after a spinal anesthetic may bear a relation to the total amount of drug used.

Curare has been used to advantage in several abdominal operations for massive hemorrhage from gastric or duodenal ulcer in which the patient was bleeding profusely and was in a state of severe shock on arrival in the operating room. Since spinal anesthesia was contraindicated because of the marked hypotension, these patients were carried on cyclopropane and curare, a technic similar to that advocated by Cullen being used. The cyclopropane provided anesthesia with a sufficiently high oxygen concentration to prevent the development of hypoxia, and the curare provided adequate relaxation — almost equivalent to that of spinal anesthesia.

The use of curare in combination with Pentothal is becoming more extensive. Bronchoscopies and esophagoscopies are easily performed with this combination. The technic should include a thorough cocaineization of the pharynx and larynx before the administration of either drug. Curare is usually given while the patient is awake, the dosage depending on the age, size and vigor of the patient. The average dose is 60 mg. The effectiveness of the curare is determined by the patient's ability to raise his head or arms from the table. When this ability is impaired, the Pentothal is administered in the usual manner. When there is no impairment in ability to raise the head, it is evident that the dosage of curare is inadequate and a second dose is administered. This technic has obviated the necessity of deep ether anesthesia for difficult endoscopies and has appreciably shortened the time for these procedures.

Recovery from the paralysis of curare appears to be in the reverse order. With increased doses, the paresis of respiratory muscles may go on to complete paralysis. This is the one great danger in its use, particularly if facilities are not readily available to overcome it with effective artificial respiration. If curare is given to a conscious patient the results may be distressing to both the physician and the patient. The patient first notices diplopia or haziness of vision and weakness of the eyelids and then starts to salivate, only to find that he is unable to move his jaws, swallow or cough. This is followed by inability to raise the head, inability to move the extremities and, finally, difficulty in breathing. These symptoms are so distressing as sometimes to produce in the patient a fear of impending death. The administration of large enough doses of curare to conscious patients to cause these symptoms is unwarranted. The drug is supposed to have no central action, but further experimental work may disprove this assumption. Whitacre and Fisher¹⁷ have shown that patients can be made unconscious by exceptionally large doses of curare. Smith¹⁸ permitted the drug to be administered to him until complete respiratory paralysis had occurred and stated that he had not lost consciousness. Fegler¹⁹ demonstrated that curare affected the respiratory center in animals before the full development of its peripheral action. Stimuli that ordinarily increase or decrease the frequency and amplitude of respiration had no effect during the period of respiratory inhibition. For many years, crude curare was found to be extremely toxic to the cardiovascular system, but this has now been proved to have been the result of impurities in the preparation. There are no electrocardiographic changes in either normal or diseased hearts during curare administration, but it must be remembered that the respiratory depressing effect may be responsible for the production of apnea and hypoxia, which in turn may aggravate cardiac damage.²⁰ The hypotension seen after curare is transient. The pulse is unaffected, and the drop in the blood pressure is only about 20 mm of mercury and usually lasts for only a few minutes. It is questionable whether this is the result of a block in transmission between preganglionic and postganglionic fibers in the sympathetic system or of poor peripheral venous return resulting from the loss of muscle tone. Curare seems to produce a temporary loss of tone and peristaltic activity of the small bowel.²¹

A safety factor in the administration of curare is the rapidity with which it is eliminated from the body. Most of it is broken down in the liver, and the remainder is excreted unchanged by the kidneys.²²

Laboratory and clinical experiences have yet to prove certain actions of curare, such as its effect on involuntary muscles, placental permeability, blood and blood-forming tissue and also its effect on cells of the central nervous system. It is thought

that its action does not extend to structures innervated by postganglionic fibers, such as the glands and smooth muscle. At any rate, no permanent pathologic change has yet been demonstrated following its use.

Curare, a nonanesthetic and nonhypnotic drug, was introduced into the field of anesthesiology because of the excellent muscular relaxation that it provided. Far too frequently, the situation has arisen in the course of an operation when the surgeon's work is hampered because of the poor relaxation of the patient. The anesthetist in despair may deepen the anesthesia to a point that is physiologically unsound and definitely detrimental to the patient. This situation need no longer exist now that curare is available. This statement is not to be construed to mean that the drug is advised as an outlet or excuse for a poorly planned or poorly administered anesthetic. On the contrary, curare is advocated by Griffith and Johnson⁶ and by Cullen²³ in a planned technic of administration in combination with cyclopropane. This means that the anesthesia can be carried in a relatively light plane and still provide adequate relaxation. The technic consists of putting the patient to sleep in the usual manner with cyclopropane and giving the first dose of curare just as the skin incision is made. Griffith⁶ originally used 100 mg (units) practically routinely as the first dose, whereas Cullen²³ advised an average initial dose of 60 mg in patients from twenty to seventy years of age. After an interval of three to five minutes, if the initial dose is found to be inadequate, an additional dose of 40 mg is administered, and if this is also inadequate a third injection, one of 20 mg, is given. The initial dose may be sufficient if the operation does not last longer than forty-five minutes. If the procedure is longer, supplementary doses should be given, a half to a third the initial dose being used. The drug has been given to both young and old patients and to those who are both good and poor risks. In small infants dosages of from 4 to 6 mg have been employed. Experience has shown that an intravenous injection is usually effective in thirty to sixty seconds and lasts about twenty minutes. The total dosage given during an operation is not too important. There will be a return of adequate respiratory excursions long before the return of muscle tonus. The one factor that must be observed closely is the effect of each dose on the respiration.

As stated above, the anesthetist must definitely be prepared to treat respiratory depression or apnea. Poor respiratory exchange must not be tolerated for any length of time because of the likelihood that a hypoxic state and the accumulation of carbon dioxide will develop. Adequate airways must be available, and in fairness to the patient, the anesthetist should have some knowledge of the technic of endotracheal intubation. This, indeed, is manda-

experience, it was found to be more advantageous to begin the administration of curare as much as five to fifteen minutes before the time of expected relaxation. This early onset of administration allowed sufficient time for subsequent doses if required, and permitted another way of administering curare—namely, by repeated small doses. When curare is given in this manner, the anesthesiologist can more closely approximate the proper dose by evaluating the response of the patient to the repeated injections of the drug, rather than depending solely on an arbitrary standard dose administered at the beginning of the operation.

Although efforts were made to use the smallest dose, varying degrees of depressed respiration and respiratory paralysis were experienced in a number of cases. The relatively narrow margin between the optimal dose and that producing respiratory paralysis corresponded to that described by Cullen.⁹ It was found that before the respiratory impairment produced by the paralysis of the intercostal muscles and diaphragm, the respirations became depressed in varying degrees. This depression appeared in several cases when the abdominal muscles were not sufficiently relaxed. This phenomenon probably results from the depressant effect of curare directly on the respiratory center. As Fegler¹² demonstrated the drug influences the respiratory center before the full development of its peripheral action.

During the administration of curare, when the respirations became depressed and the excursions of the breathing bag perceptibly decreased the respiratory movements were immediately supported by the application of manual compression on the breathing bag, the minute volume exchange being thus increased. In many cases this support to the respiration was followed by periods of apnea with controlled breathing. It would be difficult to determine how often this apnea was primarily due to respiratory paralysis produced by curare or to the so-called "apneic technic." The return of spontaneous respiration occurred on the average in ten or fifteen minutes when the general anesthesia was lightened. Nevertheless, in several cases this return of spontaneous respiration did not occur so readily as in the straight apneic technic. Controlled breathing was probably used more frequently than was absolutely necessary. This procedure seems to be justified by the following supposition: owing to the many factors that have a depressant effect on the respiratory center during anesthesia¹³ and to the additional depressing effect of curare, proper oxygenation and carbon dioxide elimination are questionable with the patient's own depressed respiration, whereas they are assured with controlled breathing.

Controlled breathing is therefore a safety measure in cases of depressed respiration in which the sufficiency of the minute volume exchange can be questioned. It is an absolute necessity in cases of

respiratory paralysis in which spontaneous respiratory exchange has ceased. Since the need of establishing controlled breathing may arise at any time, curare should be administered only by those whose technical abilities as well as practical and theoretical knowledge of respiratory physiology guarantee uninterrupted and complete oxygenation and carbon dioxide elimination during periods of depressed respiration and apnea. Equally important is the proper functioning of the anesthesia machine and other anesthesia equipment used for controlled breathing.

The principles in this discussion of respiration apply not only to the cases in this group but also to any cases in which curare is used.

The second group included cases in which a single-dose spinal anesthetic for abdominal surgery was used. The surgical procedures in these cases lasted longer than was anticipated, and the effect of the anesthetic wore off at a time when relaxation was still required. Curare was used to provide relaxation.

The following method of administration was found to be the most satisfactory. Whenever there was any indication that the spinal anesthesia had started to wear off—or if there were no such indications but the expected duration of spinal anesthesia had been reached—general anesthesia was induced with either Pentothal or cyclopropane. The patients were maintained for the remainder of the operation in a light plane of the surgical stage of anesthesia. The administration of curare was begun five to fifteen minutes before the closure of the peritoneum, or earlier if the surgeon did not find sufficient relaxation on intra-abdominal manipulation. Curare was given in doses of 20 to 50 mg every three to five minutes until complete relaxation was obtained. The total amount administered to any one patient ranged between 50 and 160 mg.

Few changes in circulation were noticed following the administration of curare in the cases in this group as well as those in the first group. Only a few patients showed a moderate and transitory decrease in blood pressure. This favorable circulatory response led to the use of the drug in the cases in the following group.

The third group consisted of poor-risk patients requiring abdominal surgery. Many of them suffered from severe, acute blood loss following uncontrollable gastric hemorrhage, ruptured ectopic pregnancy or postoperative internal hemorrhage, and others were in shock owing to advanced abdominal disease, such as perforated peptic ulcer of more than one day's duration, generalized peritonitis or volvulus with gangrenous bowel.

These patients received light premedication. While intravenous fluids and, in most cases, transfusion were being administered, anesthesia was induced and maintained in the first plane of the third stage with cyclopropane. Abundant oxygenation

For more extensive operations, the combination of curare, Pentothal and nitrous oxide has been used, these include laminectomies, splanchnicectomies and more recently, intrathoracic operations. Since this combination eliminates the employment of inflammable agents, it permits the use of high-frequency electrosurgical apparatus in the chest. Induction is carried out in the same manner as in endoscopy. Subsequent doses of curare are given at intervals of twenty to thirty minutes, according to the need for relaxation at the time. It has been our observation that the total amount of Pentothal in these cases has been decreased. Needless to say, the patient's respirations must not be so depressed that he suffers from even transient hypoxia.

* * *

In the course of a few years, curare has proved itself to be of considerable value in the field of anesthesiology. It is not to be considered a panacea to answer all problems of relaxation, but it is certainly a useful adjunct. Further investigative research will no doubt augment its clinical applicability.

Since this paper was submitted for publication a solution of pure *d*-tubocurarine has become available. This preparation is biologically assayed so that its dosage is the same volume as that for Intocostarin.

EXPERIENCES WITH CURARE IN ANESTHESIA*

SIDNEY C. WIGGIN, M.D.,† PHILIP E. SCHULTZ, M.D.,‡ AND PETER SAUNDERS, M.D.§

BOSTON

THE use of curare in anesthesia has rapidly gained popularity within the past few years. Numerous papers, which agree on its usefulness, have been published since the initial study of Griffith.¹ These papers describe different methods of administration, advantages, limitations and possible disadvantages of the drug.²⁻⁹ There have also been publications of experimental studies that give further information.¹⁰⁻¹⁴

The main purposes of this paper are to consider the indications for curare and its comparison with other agents and to present experience with the use of curare (Intocostarin®) in 450 cases. The basis of discussion of the results in these cases lies in the segregation into four distinct groups in which

the special qualifications and the adaptation of curare are described. It will be noted that other uses of curare — for example, in bronchoscopy and cesarean section — are not considered.

The first group in which curare was administered comprised cases of elective abdominal surgery in which the choice of anesthesia presented no particular problem, for these cases were adaptable for any conventional type of anesthesia. With this group as a standard it was possible to evaluate the technique.

The method of administering curare with a light general anesthetic was that described by Cullen.² The agents used with curare were cyclopropane, Pentothal Sodium, nitrous oxide, ether and various combinations. The experiences and results corresponded with those of Cullen. Relaxation was found to be extremely satisfactory, in most cases, it was similar to the complete relaxation attained in spinal anesthesia. In quite a few cases, however, the onset of relaxation was delayed, additional doses and time being required. On the basis of this

pressure, pulse and respirations showed little change throughout the operation. The patient left the operating table 20 minutes after the last dose of curare had been given. The breathing was approximately normal in depth, at a rate of 28 per minute. There was no obstruction, and the respiratory exchange was good. The patient's color was good. The blood pressure was 120/68, and the pulse 122.

The transportation from the operating room to the ward took about 12 minutes. On arrival in the ward, the patient was extremely cyanotic and did not breathe, although the pulse was satisfactory. Following artificial respiration for 30 minutes, she regained spontaneous breathing but remained comatose. With inhalation and shock therapy and administration of stimulants her condition improved. Six hours after operation, the blood pressure was 98/70, the pulse 124, and the respirations 36. The patient had a corneal reflex, and, on stimulation, moved her head. Two hours later, she went into shock. She expired 12 hours after operation.

It seems probable that the main cause of death in this case was that, in her serious general condition, the patient was subjected to severe hypoxia during the transportation. The asthma may have played a role in further aggravating the failing oxygenation. Unfortunately, the intern accompanying the patient on her way back to the ward did not recognize the respiratory obstruction, which in all probability was the cause of the hypoxia.

* * *

The choice of anesthesia for elective abdominal surgery in good-risk patients up to the introduction of curare was either spinal or deep general anesthesia, with or without the use of an intratracheal tube, other methods, such as intravenous and local anesthesia and varying combinations, were rarely employed. Curare with light general anesthesia now presents another choice. Our experience with the cases of the first group led to the conclusion that the order of choice of anesthesia is as follows: spinal anesthesia, light general anesthesia with curare and deep general anesthesia or other methods. Spinal anesthesia is still superior to any other methods for this type of surgery. Its simplicity, reliability and efficiency remain unsurpassed. If light general anesthesia with curare is compared to deep anesthesia or other techniques, it is our impression that the more favorable effect on the patient and the greater ease of administration make the former method preferable to the latter.

The problem of managing the cases in which the spinal anesthesia is wearing off and the intra-abdominal surgery is continuing has been simplified by the introduction of curare. In the cases in which a spinal anesthetic does not provide sufficient relaxation with the aid of a light general anesthetic, either curare must be added or the light general anesthesia must be deepened to obtain relaxation. The obvious advantages of the method employing curare are that the depression of the general condition of the patient is avoided, with a recovery period that is shorter and freer from complications, and that control of the problem is obtained with relative ease.

The use of curare in the anesthesia of poor-risk patients introduces a new variation of balanced anesthesia. By the use of light cyclopropane anes-

thesia with small doses of curare, this method employs the principle of balanced spinal anesthesia described by Wiggin.¹⁷ In both methods, two agents are administered in small amounts and are well tolerated by the handicapped patient. Since these agents act on different structures—the central nervous system and the neuromuscular junction and, in the balanced spinal anesthesia, the central nervous and peripheral nervous systems—their anesthetic effect is cumulative. Thus, satisfactory anesthesia can be accomplished by their balanced use with small doses that, if used alone, would be insufficient. The possible systemic effect of these low dosages is apparently not cumulative and seems to remain below the point where it would affect the general condition of the poor-risk patient to any appreciable extent. The administration of light cyclopropane anesthesia with curare or in balanced spinal anesthesia is similarly accompanied by the simultaneous administration of high percentages of oxygen and fluid therapy. This new variation of balanced anesthesia seems to be a valuable method for these types of patients.

The use of curare to facilitate intratracheal intubation adds another method to the various techniques of preparing patients for intubation. The advantage of this procedure is that it allows the anesthesiologist to use a light level of general anesthesia and to obtain complete relaxation in a relatively short time. The possible respiratory embarrassment following intubation is a disadvantage.

Postoperative complications that are respiratory in origin emphasize the importance of the physiologic control of respiration during the operation and the necessity of the same careful supervision of the patients who are under the effect of curare in the postoperative period.

was provided throughout the operation. The curare was administered in doses of 20 to 50 mg every three to five minutes, until the surgeon reported satisfactory relaxation. The total dose required in some cases was less than 50 mg, whereas other cases required as much as 120 to 150 mg during the operating time of two or three hours. The resulting operating conditions were satisfactory.

Light cyclopropane anesthesia with properly administered curare did not seem to burden the handicapped circulation of these patients by adding to the present or impending shock. On the contrary, by the addition of fluid therapy and the tonic action of cyclopropane with high oxygen percentage, the general condition of most of the patients improved during the operation. The clinical course in the cases in which subtotal gastrectomy was performed on patients with uncontrollable gastric hemorrhage was as gratifying as that of a similar case reported by Whitacre.⁵ Although several patients in this group were moribund before the operation, there was no death during the operation or during the immediate postoperative period.

The fourth group comprised patients who required endotracheal anesthesia. Curare was given to facilitate the intubation by relaxing the jaw and throat musculature.

The following method of administration was found to be the most satisfactory. Cyclopropane or Pentothal anesthesia was induced, and curare was simultaneously administered in doses of 20 to 50 mg. The first dose was given at the time when anesthesia started, and further doses were given every three or four minutes. Within eight to ten minutes the patient was in the lower first or upper second plane of the third stage, relaxed and breathing quietly with sufficient depth. The intubation, which took place at that time, was easy and smooth in the majority of cases.

There were, however, respiratory disturbances of minor significance following the intubation in a certain number of cases. The regular rhythmic breathing sometimes stopped, and there was complete cessation of breathing, interrupted with occasional jerky inspirations. This respiratory embarrassment lasted in most cases for a few minutes, although there was one case in which it lasted for thirty-five minutes. In some cases, while controlled breathing was being administered during this period of respiratory embarrassment, the inflation of the lungs met with resistance, indicating that the patient was having a bronchial spasm. Whitacre⁵ and Griffith¹⁶ call attention to the fact that bronchial spasm occurring during curare administration is due to insufficient depth of the general anesthesia, in addition to the presence of a gross stimulus. The stimulus in these cases was the intubation and the tracheal tube lying in the trachea. In other cases the lungs could be readily inflated, indicating that the apnea was due to respiratory paralysis,

which developed during or immediately following the intubation. To avoid such respiratory disturbances, it seems necessary to stay within a narrow margin of proper depth of general anesthesia and of proper dosage and timing of curare.

The administration of curare for intubation in such a manner that the patient is deliberately put into apnea, the intubation taking place during apnea, has the disadvantages that during the intubation the controlled breathing—that is, the oxygenation of the patient—is interrupted and that it is difficult to re-establish spontaneous respiration with sufficient depth of the general anesthesia, both of which may be necessary in intrathoracic operations.

If ether is used as the main anesthetic for the ensuing operation, its administration, in the form of a slow addition to the cyclopropane or Pentothal, may be started before or after intubation. The amount of ether used in such cases need not exceed a third or a fourth of the amount that would be required if curare were not used. An hour and a half to two hours after the intubation is necessary before the ether requirement approximates the usual amount.

The recovery period in cases of all the groups was generally uneventful and brief, corresponding to the findings of others. Three cases, however, presented complications during recovery. Two of these showed postoperative respiratory depression. One patient, who had received cyclopropane and a small amount of ether with curare, recovered four hours after the operation. The other, who had received a spinal anesthetic followed by cyclopropane and curare, had a recovery period lasting seven hours. These patients were in shock, with depressed breathing and with depression of the reflexes during the postoperative interval. They recovered gradually and completely. Neither the surgery performed nor the anesthetic administered seemed to give sufficient reason in either case for this postoperative complication. It appeared reasonable to assume that hypoxia, which probably developed during the period of shallow breathing following the administration of curare, was an important cause. In these cases, which occurred at the beginning of the series, the anesthesiologist did not support the patient's spontaneous shallow breathing. The experiences with these cases in particular led to the conclusion that depressed respiration should be managed as described above.

In the following case postoperative depression was followed by a fatal outcome.

M. M., a 57-year-old woman with bronchial asthma, was operated on for intestinal obstruction of 4 days' duration. Her general condition before operation was fair. The operation included an extensive exploration, a lysis of adhesions and an ileocecostomy. A spinal anesthetic was administered and was supplemented with Pentothal and curare after 1 hour and 25 minutes. Curare was given in repeated doses totaling 100 mg. During the operation, 100 per cent oxygen was administered, and a transfusion was given. The blood

of other causes without recurrence the five-year cure rate is 89 per cent for patients without involvement of the lymph nodes, 34 per cent for those with lymph-node involvement and 50 per cent for the whole series. We are convinced that the complete radical operation should be done at the time of the first surgical approach to a cancer of the breast.

Three of the 6 patients on whom simple mastectomies were performed are without present evidence

nodes over 2.5 cm in diameter all or nearly all lymph nodes involved and signs suggesting a possible inflammatory type. We believe that wide removal of skin minimizes local recurrences, but unless one is too selective in choosing cases for operation a few recurrences are inevitable.

The extent of involvement of the axillary lymph nodes is of great prognostic significance, as shown by Warren and Tompkins⁶ in a study of cases from

figures at Presbyterian Hospital² represent the clinical cures divided by the number of operations. Ten, or 14 per cent, of the patients in whom radical mastectomies had been performed developed local recurrences, some of them after five years. Other published series have varied in this factor from Rodman's⁵ 2.2 per cent to Haagensen and Stout's⁷ 22.8 per cent. There were no recurrences of cancer in the axilla in our series. An analysis of our cases disclosed that in all but 2 in which neoplasm reappeared in the operative field there were features of questionable operability, such as axillary lymph

nodes with 48 per cent cures, and 24 cases of Grade III, with 37 per cent cures.

One hundred and twenty-five patients in whom mastectomies had been performed elsewhere were followed in our clinic. In a few, radical operations had been performed at the Massachusetts State Cancer Hospital in Pondville, and the patients had been transferred merely for routine examination. Most of them had been operated on in various local hospitals and had been referred to us for x-ray treatment.

CARCINOMA OF THE BREAST

A Review of the First Three Years' Experience in the Cancer Section of the Westfield State Sanatorium

FREDERICK S. HOPKINS, M.D.,* AND NICHOLAS EGNATZ, M.D.†

WESTFIELD, MASSACHUSETTS

TWO hundred and fifty-eight patients with carcinoma of the breast were seen in the Cancer Section of the Westfield State Sanatorium in its first three years, 1938 through 1940. In 70 cases a radical operation was done in hope of cure. Simple mastectomies were performed in 7 cases, whereas 138 patients were referred after having been treated at other hospitals.

Thanks to an extremely efficient social-service department, all these patients have been followed. All except 4 of the surviving patients who were operated on are still being regularly examined at the clinic, and the others have been visited by one of the social workers.

Our routine procedure at the time of the first visit of a patient with suspected cancer of the breast consisted in x-ray films of the chest, as well as the upper ends of the humeri, the skull, the spine and the pelvis, including the upper ends of the femurs. Unsuspected metastases have been found in several cases that would otherwise have been deemed operable. Other contraindications that we have followed are fixed, matted lymph nodes in the axilla and definite inflammatory carcinoma. If there is any suspicion of involvement of the supraclavicular nodes, a biopsy is done first. In this series the patient's general condition has not been considered a contraindication to operation, although most of the simple mastectomies were done because of poor physical condition. There were deaths in 3 cases after radical operations, however, and 1 fatal case following a simple mastectomy—all in patients over seventy years of age and in poor physical condition. Johnson and Lombard¹ have shown that the operative mortality in cancer is directly proportional to age. Since then we have more carefully evaluated patients in the older age group and refer them for radiation treatment unless we believe that they have a life expectancy of at least five years. After this procedure had been adopted, there were no postoperative deaths.

The operations were performed by thirteen members of the visiting and resident staffs. Most operations began with a local excision of the tumor and a frozen section to confirm the diagnosis. A formalin-soaked sponge was placed in the cavity before suturing, and the wound was sealed with collodion and gauze. The usual incision was of the Rodman-

Greenough type. We believe, however, that the important feature is to make the incisions include an area of skin at least as wide as the breast and with the tumor at least 5 cm from the incision. After the pectoral muscles have been divided at their insertions, a meticulous dissection of the axilla is made, all areolar tissue being removed from the axillary vein. The upper rectus fascia is removed with the breast, muscles and axillary contents. Wide undercutting usually permits closure without grafting. The value of thorough, extensive dissection is clearly illustrated by the report of Haagensen and Stout,² who found no statistically significant difference in the results of various types of radical mastectomies. But the cure rate was in direct proportion to the duration of the operation. The rate for procedures lasting less than an hour was 28.6 per cent, whereas for each successive hour of operating time it was 35.3, 34.3, 43.7 and 56.3 per cent respectively.

Preoperative x-ray treatment was not used, but all patients with axillary metastases were given postoperative radiation. The usual dose was 7200 r. Four portals were employed, 1800 r being given to a 10-by-15-cm supraclavicular area, to a 10-by-10-cm axillary area, to a 10-by-15-cm posterior axillary area and to a 15-by-15-cm area on the anterior chest wall. The other factors were a constant potential of 200 kilovolts, a wave length of 0.16 angstrom, a distance of 50 cm, and a filter of 1 mm aluminum and 0.5 mm copper. Women who were still menstruating were offered ovarian radiation, which most of them accepted.

In the determination of results, operative deaths and patients alive with recurrence were classed as failures. Of the 70 patients who had radical operations 30, or 43 per cent, are living and well without evidence of cancer. Of the 45 cases with axillary metastases 14, or 31 per cent, are considered five-year cures. When no involvement of the axillary lymph nodes was found 16 of 25 patients, or 64 per cent, are living and well (Table 1). Three of the deaths, however, were from other causes without evidence of recurrence. With the elimination of these cases the cure rate is raised to 73 per cent. Nine of the 70 patients with radical operations had had either a simple mastectomy or local excision of a tumor before being referred to us. Of these only 3 cases are considered clinical cures. Five patients showed no evidence of axillary metastases. If these are eliminated, as well as those dying

*Director, Cancer Section, Westfield State Sanatorium, visiting surgeon, Springfield Hospital.

†Formerly assistant superintendent, Cancer Section, Westfield State Sanatorium.

cancer, are factors indicating a poor prognosis. The percentage of axillary lymph nodes showing metastasis and the microscopical grade of the tumor are also of valuable prognostic significance. It is dangerous to rely on the clinical impression regarding the involvement of the nodes. In 11 cases the pathologist found metastases that were not diagnosed clinically, whereas in 3 the nodes were considered involved but no metastases were found.

This series does not permit any significant evaluation of x-ray treatment. The patients with involvement of the axillary lymph nodes gave us slightly better results than those in most of the published statistics, and all of them were given postoperative radiation. We do not believe, however, that the results can be attributed to the radiation. All except one of the patients who developed local recurrences had had x-ray treatment. We believe that the patients who received only palliative x-ray treatment were made much more comfortable and that there was some prolongation of life. We have recently omitted routine postoperative x-ray treatment of patients with axillary metastases.

SUMMARY

Two hundred and fifty-eight patients with cancer of the breast seen at the Cancer Section of the Westfield State Sanatorium over five years ago are reviewed. Fifty-nine, or 23 per cent, were considered five-year clinical cures. Thirty, or 43 per cent, of the 70 patients who had radical mastectomies at Westfield are alive without evidence of recurrence five to eight years following operation. Ten, or 14.5 per cent, of this group had local recurrences. There was no case of recurrence in the axilla. Twenty-two, or 18 per cent, of the group that we

followed who had had radical mastectomies elsewhere are apparently cured.

The observance of the operative criteria proposed by Haagensen and Stout would improve the figures of five-year survivals but would allow an occasional patient to receive only palliative treatment when there was a possibility of obtaining a cure. These criteria are of prognostic value.

The percentage of lymph-node involvement and the microscopical grade of the tumor are of aid in prognosis.

X-ray treatment is of great help in making the patient more comfortable.

The value of a complete radical operation at the time of the first surgical approach to cancer of the breast is illustrated by the fact that whereas our percentages of five-year clinical cure were 73 per cent with negative nodes, 31 per cent with axillary metastases and 45 per cent for the series, by the elimination of patients who had previous operations the corresponding percentages were 89, 35 and 50 per cent.

Twenty-two, or 18 per cent, of these 125 cases were considered five-year clinical cures. Of the 42 cases without evidence of axillary metastases 10, or 24 per cent, were apparently without recurrence, whereas of the 61 with extension to the lymph nodes only 10, or 16 per cent, were without evidence of carcinoma after five years. There were 22 cases in which there was no definite information concerning the status of the lymph nodes. Only 4, or 3 per cent, of the entire group developed local recurrences.

Forty-seven patients were considered inoperable when first seen and were treated by x-ray only. Of these, one is regarded as a five-year clinical cure and 2 have passed the five-year mark but have developed recurrences. The average length of life in this group was thirty-six months from the onset of the disease. These cases cannot be compared with Daland's⁷ series of untreated cases in which the average length of life was forty and a half months, because only the advanced cases were treated exclusively by x-ray therapy.

Haagensen and Stout⁸ have made a careful study of the criteria of inoperability and of factors of poor prognostic significance. The following are considered definite contraindications to operation: distant metastases, inflammatory type of carcinoma, supraclavicular metastases, edema of the arm, intercostal or parasternal nodules, satellite nodules in the skin over the breast, extensive edema of the skin over the breast and carcinoma developing during pregnancy or lactation. They obtained no cures in this group, which they call "categorically inoperable." Other factors of such poor prognostic significance that the presence of any two is regarded as a contraindication to operation include ulceration of the skin, limited edema of the skin (less than a third), fixation of the tumor to the chest wall, axillary lymph nodes measuring 2.5 cm or more in the transverse diameter and proved to contain metastases by biopsy and fixation of axillary lymph nodes to the skin or the deep structures of the axilla, with the nodes proved to contain metastases by biopsy.

Although we have always considered inflammatory carcinoma to be a contraindication to operation, there was 1 operative case that was apparently of the inflammatory type. This promptly recurred. Two patients had redness of the skin and slight local heat. Each had some other feature of questionable operability. One of these is living and well. In 1 patient the axillary lymph nodes over 2.5 cm in diameter with questionable fixation were found to be merely inflammatory, and there is no evidence of recurrence. The 12 other cases with various combinations of ulceration, limited edema, fixation to the chest wall, satellite skin nodules, axillary lymph nodes over 2.5 cm in diameter, questionable fixation of nodes, preoperative edema of the arm or redness of skin or local heat are all considered failures.

The other factors mentioned by Haagensen and Stout did not occur in this group.

A thorough statistical review of 570 cases of carcinoma of the breast with radical mastectomies in 350 has recently been made by Wells,⁹ of the Hartford Hospital. Two of the 3 cases in which cancer developed during pregnancy or lactation were classified as ten-year cures. In the group in which two factors of poor prognostic significance were considered a contraindication to operation there were a few scattered cures in both series except when either multiple tumors or skin edema was combined with other factors. In the group that would be classified as inoperable by Haagensen and Stout,⁸ Wells⁹ had 57 cases of which 8, or 14 per cent, were considered five-year clinical cures, and 7 apparently permanent cures. Harrington,⁴ of the Mayo Clinic, reported 99 operated cases of cancer of the breast developing during pregnancy or lactation, with axillary metastases in 84.8 per cent. In this group the five-year and ten-year survivals were 7.7 and 3.1 per cent, whereas in those without axillary metastases the figures were 57.1 and 38.5 per cent respectively.

DISCUSSION

Although this is too small a series to be statistically conclusive, we believe that it emphasizes certain important facts. One cannot repeat too often that a thorough radical operation will cure most cases of cancer of the breast if performed before there are axillary metastases. In our cases in which the lymph nodes were already involved 31 per cent of patients are alive without evidence of cancer. A total five-year salvage of 43 per cent in all our radical operations is encouraging. This figure could be improved slightly by more strict adherence to Haagensen and Stout's criteria. We believe, however, that every case in which there is a possibility of cure should have the benefit of operation. We accordingly operate on many poor-risk patients except those with an estimated life expectancy of less than five years. Enough good results have been obtained in patients developing cancer during pregnancy or lactation to justify the attempt. Unless large axillary lymph nodes are firmly fixed, operation might obtain a good result, and the case should certainly not be classified as inoperable without a biopsy of the nodes. When the finding of satellite nodules, multiple tumors or skin edema is combined with other unfavorable features, there is too slight a possibility of cure to warrant operation. We agree that distant or supraclavicular metastases, inflammatory carcinoma, preoperative edema of the arm, intercostal or parasternal nodules and extensive edema of the skin are contraindications to operation. The other features, such as redness, ulceration or limited edema of the skin, fixation of the tumor to the chest wall and large or adherent axillary lymph nodes showing

dilated lateral ventricles were visualized that were highly suggestive of hydrocephalus internus. Some air was also observed to be trapped in the region of the cisterna magna, which appeared much larger than normal. Briefly, the films were consistent with generalized cortical atrophy, hypoplasia or aplasia of the cerebellum and possibly, internal hydrocephalus.

Lumbar puncture was repeated on January 3, and analysis of the cerebrospinal fluid showed a total protein of 234 mg per 100 cc.

The temperature began to exhibit wide fluctuations on January 4 and 3 days later reached a maximum in excess of 105°F. Enemas, clyses, sponges and the ingestion of acetylsalicylic acid were followed by a reduction in temperature. The infant was having fourteen loose green stools a day by January 9 and was put on fluids and sulfadiazine. On January 11 the red-cell count was 2,560,000, and the white-cell count 6600, the temperature became more regular, and the diarrhea showed signs of abating. The intravenous administration of 10 cc. of whole blood, however, failed to effect an improvement in the red-cell count.

On January 14 the patient developed nuchal rigidity, convulsions, spastic movements of the extremities, opisthotonos and an elevated temperature, without, however, exhibiting bulging fontanelles. Cerebrospinal fluid obtained by lumbar puncture was clear, with a total protein of 85 mg per 100 cc, no leukocytes and a few crenated and noncrenated red cells, culture showed no growth after 72 hours. Symptomatic therapy resulted in significant improvement and the course was uneventful until February 10, when diarrhea again developed. A site of infection was not found, but routine therapy with fluids and sulfadiazine was again followed by improvement. The weight gain continued to be satisfactory. Fluctuations in temperature, never entirely absent again became marked, the temperature periodically dropping as low as 93°F.

Re-evaluation of the patient at 4 months of age showed paralysis of the right leg extending to and including both gluteal muscles and no alteration in the talipes equinovarus of the right foot. The left leg was better developed and had more substance, but it was far from normal. The pilonidal sinus was still clearly evident. The lesions on the skin of the left thigh were white, raised and slightly irregular. A severe torticollis to the right was present, and only by force could the head be maintained in normal position. The eyes exhibited continuous lateral nystagmoid movements. Ophthalmoscopic examination revealed bilateral optic atrophy and a peculiar darkish pigmentation of the retinas. On the whole, the patient appeared abnormally quiet and inactive.

A glucose-tolerance test done on April 17 showed the blood sugar to be 89 mg per 100 cc. fasting, 160 mg at 30 minutes, 129 mg at 1 hour, 125 mg at 2 hours and 127 mg at 3 hours, no urinary sugar was found during the test period.

Except for the sudden appearance and remission of spasticity, vomiting and bulging fontanelles on March 15 not due to meningitis, the course continued uneventful, and the patient was discharged on April 29 under the supervision of the Social Service Department.

Although a purely pathological diagnosis is not feasible in this case, it may prove interesting to list the defects that may justifiably be considered to have been present: talipes equinovarus, right, paralysis and muscular atrophy, right lower extremity, defective development, toes of right foot, cortical atrophy, hypoplasia or aplasia of cerebellum, internal hydrocephalus, bilateral optic atrophy, pilonidal sinus, torticollis to right, cicatricial (? post-varicella) lesions, skin of left lower extremity, undescended testicle, left, and insufficiency of anal and vesical sphincters.

In addition, certain defects of a preponderantly physiologic nature were noted, such as hyperirritability of the central nervous system, poorly functioning thermoregulatory ability and an apparent increased susceptibility to infection.

DISCUSSION

The case presented above is one in which a well authenticated episode of maternal varicella complicating the eighth week of pregnancy was followed by term delivery of an infant with extensive developmental defects. The maternal and paternal family

histories were devoid of congenitally malformed offspring. A three-year-old sibling of the patient was normal. Apparently, then, constitutional factors may be minimized as contributing to the etiology of the multiple defects, whereas the possibility is enhanced that the prenatal varicella was the responsible agent. As Conte, McCammon, and Christie³ point out, however, it is difficult to evaluate the significance of reported cases because it is not known how often virus infections occur without congenital malformations or how often malformations occur without virus infections—in other words, there are no controls for the reported cases. An effort was made to determine the frequency with which maternal gestational varicella was followed by offspring with such severe congenital defects, but in a review of the literature no similar reports could be discovered. At this writing, the case detailed above is apparently the first of its kind to appear in the literature, although we may be unacquainted with pertinent prior papers. In this connection, however, it may be interesting to quote, in toto, a case cited by Conte, McCammon and Christie³ together with their comment:

Case 7. J. M., a white boy, was born at term of a 23-year-old mother, who had chickenpox in the second week of her pregnancy. Delivery was normal. His immediate neonatal condition was good. His birth weight was 7 pounds (3,175 gm). There was no congenital anomaly found in this infant. The varicella occurred in the first month and was not followed by a congenital anomaly in the child. There have been no previous observations made concerning the relationship between this disease and congenital anomalies.

Failure of this infant to demonstrate defects does not necessarily negate or modify the possible propensities of maternal gestational varicella for the production of anomalies. In the first place, the disease was contracted in what was apparently the second week of pregnancy, however, since estimated dates of conception are notoriously inaccurate, it is possible that the mother did not actually become pregnant until after the disease had been experienced. Swan and Tostevin⁶ remark the absence of congenital defects following rubella that occurs just before pregnancy. Again, the third principle of Stockard⁷—cited below—may have been operative. A final explanation, which admittedly cannot be definitely excluded at present, is that maternal varicella bears only a coincidental and not an etiologic relation to subsequent infantile anomalies.

More or less incidentally in a paper concerned chiefly with the relation of maternal gestational rubella to congenital defects, Swan and Tostevin⁶ mention 2 cases of pregnancy complicated by varicella, in both of which the mothers contracted the disease in the seventh month. One of the infants born subsequently was normal, the other had a nevus of the scalp, and the x-ray findings were suggestive of a cardiac defect—an enlarged heart, a small aorta and configurations indicating right

MULTIPLE CONGENITAL DEFECTS FOLLOWING MATERNAL VARICELLA*

Report of a Case

EUGENE G. LAFORET, A B,† AND CHARLES L. LYNCH, JR., B S‡

CAMBRIDGE AND BOSTON

INVESTIGATION of the factors responsible for congenital malformations received tremendous impetus in 1941 with the classic report by Gregg,¹ of Australia, of a series of cases in which maternal rubella was followed by a variety of anomalies in the offspring, particularly such ocular defects as cataract. Previously, it had been generally accepted that malformations do not result from environmental factors that operate for the first time after fertilization.² Attention, therefore, had been directed chiefly at possible preconceptual causes. The studies of Gregg¹ and of numerous subsequent workers, however, emphasized the necessity of according careful consideration to environmental conditions obtaining after the fetus has become established.

The significance of this newly adopted approach to the problem of congenital malformations is already well recognized, and a voluminous literature has sprung up since the initial publication from Australia. Considered from the aspect of preventive pediatrics, therefore, the potentialities of continued work in this field are gratifying.

The maternal virus disease that thus far appears to be the most frequent offender is rubella. In 1945 Conte, McCammon and Christie³ collected 136 cases of congenital malformation with a definite history of maternal prenatal virus infection, in all but 2 of which rubella was the associated disease, a case of mumps and one of influenza constituting the exceptions.⁴ On the basis of analogy, however, the suspicion is growing that the incidence of congenital malformation following other maternal prenatal virus infections parallels that associated with rubella. This is suggested by Fox and Bortin,⁵ who recommend more extensive investigation of the possible relation of congenital malformations to any of the virus diseases that occur during gestation. In the following case maternal varicella occurring in the eighth week of pregnancy was followed by delivery of a child with extensive congenital defects.

CASE REPORT

A 6-hour-old infant (B F H 90816) was admitted to the hospital on October 27, 1945, because the attending physician had detected an anomaly of the right leg. The mother, a 23-year-old housewife, had had pertussis, rubella and asthma in childhood, at the age of 7 or 8 years she had been unable to bear weight on her legs and was presumed to have had

rickets at that time. So far as could be ascertained, there was no family history, either maternal or paternal, of congenital anomalies. The mother had contracted varicella in the 8th week of pregnancy, when she was "covered from head to foot" with lesions and had a temperature of 102°F for two weeks. The diagnosis of varicella was well established, since the case had apparently been a classic one. A 3-year-old female sibling of the patient had also had varicella synchronously with the mother. The course of the pregnancy had been normal except for an occasional whitish vaginal discharge that was more marked in the morning. The gestation proceeded to term, delivery being by vertex and spontaneous.

Physical examination revealed a poorly developed, normally nourished infant. The skin was pinkish and normal except for several well defined reddish pigmented areas, 3 to 5 mm in diameter, on the medial aspect of the left thigh and leg. The head was round and regular. The eyes showed only questionable reaction to light. The scleras and conjunctivas were clear. There was no nasal discharge. Otoloscopic examination disclosed normal tympanic membranes bilaterally. The oral cavity and oropharynx were normal. There was no nuchal rigidity or cervical lymphadenopathy. The lungs were resonant and clear. The heart was not enlarged to percussion, and no abnormality of rate, rhythm or sounds was detected. The abdomen was soft. The liver was palpated three finger-breadths below the right costal margin. The spleen could not be felt. No costovertebral swelling or other abdominal masses were discovered. Grossly the external genitalia appeared normally developed except for an undescended left testicle, but urine constantly dribbled throughout the examination. The anal sphincter, which was at the level of the buttocks, was relaxed and widely patent, presenting a continuous discharge of fecal material. The extremities were normal except for the right lower leg, which was thin and underdeveloped in comparison with its mate, and a right talipes equinovarus, the toes of the right foot were underdeveloped, the terminal phalanges being represented only by small horny pegs, and the great toe was in abnormal apposition. The muscular atrophy of the right leg extended to the gluteal region. The deep tendon reflexes were physiologic except for an absent knee jerk on the right and an unelicitable Achilles reflex on the right. In the lumbar region there was a longitudinal depression, 3 cm in length and 0.5 cm in depth, that was free of discharge. Routine urinalysis and blood counts on admission were not remarkable.

X-ray studies on October 29 revealed no evidence of increased intracranial pressure or of any abnormality of the vertebral column. A chest plate was normal. Films of the right leg and foot were reported as follows:

The right lower extremity is markedly underdeveloped. The bone is retarded in development and the soft tissues have an abnormal appearance. The foot is particularly deformed, the 4th and 5th toes having only a basal phalanx and no middle or end phalanges. The size of the individual bone is but a fraction of that of a normal one. This is obviously a congenital anomaly of a developmental character.

The right leg showed no improvement and apparently was not growing. Actively, it could not be fully extended at the knee, and even passively could not be fully flexed at the hip. Measurement on December 10 revealed it to be 2 cm shorter than the left.

After two previous attempts at lumbar puncture had resulted in bloody taps, a third on December 19 was satisfactory, analysis was essentially normal except for a total protein of 160 mg per 100 cc. Bilateral subdural taps were also done on this date and disclosed a large amount of clear fluid, also with a high protein content (117 mg per 100 cc).

On January 2, 1946, a pneumoencephalogram was performed, 30 cc of air being injected over a period of 2 hours after the withdrawal of 35 cc of cerebrospinal fluid. Large

MEDICAL PROGRESS

EFFECTS OF PROTEIN DEFICIENCY ON THE PREGNANT WOMAN AND FETUS AND ON THE INFANT AND CHILD (Concluded)*

HAROLD C STUART, M D †

BOSTON

PROTEIN DURING INFANCY AND CHILDHOOD

Requirements

The primary function of protein in the diet is to provide the amino acids that are essential for the synthesis of tissue proteins characteristic of the species. In normal adults, new tissues are required only for replacement or maintenance. Disease and trauma may cause a rapid loss of nitrogen and greatly increase the need for protein at any age. In infants and children three additional factors must be considered. The young person differs from the adult in that he is immature, he is small, and he is growing. For the most part, infants and children utilize protein well, but normal infants and especially premature infants need protein in a physical form that their digestive tracts can readily assimilate. Levine³⁵ in a recent review, cited an example of the influence of immaturity on protein needs. The premature infant has difficulty digesting and absorbing fat and tends preferentially to use protein, as well as carbohydrate, to provide energy, thus increasing protein requirements. Although immaturity undoubtedly increases the margin that must be provided over and above actual tissue requirements, this characteristic of early life is not a major one in determining total protein needs. Body size influences to some degree the amount of protein that must be provided when requirements are considered on the basis of unit of body mass. The relation of total maintenance or basal needs to body size is not a direct one of straight-line progression, and hence the basal needs are not the

same per kilogram of body weight irrespective of size or age. This is apparently due to a relation between the basal caloric and protein requirements. It is well known that the smaller the animal, the higher the energy requirement on the basis of body weight. This need is more constant when based on a unit of surface area, which is relatively greater, the smaller the body mass. Hegsted³⁶ has pointed out that the protein requirement for maintenance is much more closely correlated with basal energy requirement than with body size. This is understandable since a high basal metabolic rate is associated with a high catabolism, and more materials are therefore required for anabolism. Total protein needs per kilogram of body weight are much higher in infancy than in childhood and somewhat higher in childhood than in adolescence, part of this difference, although as yet an undetermined one, is undoubtedly due to the relation of maintenance need to body size. The influence of growth on protein requirements in early life is the principal effect with which this discussion is concerned. Levine³⁵ points out that in infancy and childhood both the quality and the quantity of dietary protein must be adequate to cover growth requirements as well as maintenance needs, under which he includes the allowance for fecal loss. This loss averages between 10 and 15 per cent of the total protein at all ages but varies with the type and amount of protein food consumed and with the functioning of the digestive system. He emphasizes the fact that protein requirements are greatly influenced by the adequacy of the caloric intake.

Several studies on animals have shown that normal growth of the young depends on the provision of suitable proteins and that quantitatively equal amounts of different proteins result in different rates of growth depending on the biologic value of the

*From the Department of Maternal and Child Health, Harvard School of Public Health.
This review was prepared for and presented in part at A Symposium on "Protein" at the celebration of the one hundredth anniversary of the University of Buffalo, September 27, 1946.

ventricular preponderance. In both cases the disease occurred well beyond the period (first trimester) when congenital defects are most to be feared, and in the significant case the defects were neither severe nor extensive.

Carefully to be distinguished from congenital anomalies following maternal varicella (teratogenic varicella) is congenital varicella, in which the pathogenesis of the disease in utero closely parallels the course it pursues in its better known guise as an almost inevitable but relatively benign childhood exanthem. There have been numerous references to the occurrence of varicella in the newborn,⁸⁻²¹ some better substantiated than others, in these cases the mothers contracted the disease near term and presumably transmitted the virus transplacentally, the child either being born with a fully developed vesicular eruption or developing it so soon after birth that sources of infection other than intrauterine could be discounted.

To cause severe developmental defects varicella or other virus disease must apparently occur in the first trimester of pregnancy. Goodpasture believes that this susceptibility during early pregnancy may be due to the fact that young and relatively undifferentiated cells are a more propitious medium than mature cells.

In this connection, three experimental conclusions of Stockard⁷ cited by Swan and Tostevin⁶ are presented as being particularly applicable.

The type of abnormality is determined by the particular developmental "moment" at which the noxa acts. At different periods in the development of the ovum, certain primordia are undergoing rapid proliferation, and may be thought of as developing at a rate entirely in excess of the general developmental rate of the embryo. At such periods these primordia are peculiarly susceptible to unfavourable influences, while only slight or no ill effects may be suffered by the embryo as a whole.

The earlier the arrest the more numerous will be the types of defect found, and the later the arrest the more limited the variety of deformities, since there are fewer organs to be affected during their rapidly proliferating primary stages.

If development is arrested or retarded at a stage when no unusually rapid changes are taking place, a comparatively quiescent moment during which all parts are developing, but during which no particular or important part is proliferating at an excessively high rate, the embryo may escape injury.

Regarding the last conclusion of Stockard, Swan and Tostevin state "If such 'moments of indifference,' as Stockard calls them, occurred in the earlier months of pregnancy, they would serve to account for the (so far) rare cases in which mothers have contracted rubella during these months and yet have given birth to apparently normal infants."

Perhaps the first reference to congenital anomalies following maternal virus disease is the rather esoteric observation attributed by Lynch²² to Watson,²³ who, in a paper published in 1749, stated that the fetus "was liable to be infected [with variola] at a very different time and in a very different manner from the mother." The potentially teratogenic aspects

of maternal rubella are receiving increasing emphasis and are well known. Congenital anomalies have been reported following mumps,⁴ herpes zoster,⁵ rubeola⁶ and influenza.⁴ Conte, McCammon and Christie,³ after reviewing the literature, could find no reference to congenital malformation subsequent to maternal varicella, although the case reported above and the most recent survey by Swan and Tostevin⁶ indicate that such an occurrence is possible. Waaler²⁴ has discussed 8 cases of acute anterior poliomyelitis in pregnant women between eighteen and thirty-eight years of age, without the occurrence of fetal malformations. Nevertheless, in a review article concerned primarily with maternal rubella, Aycock and Ingalls²⁵ incidentally mention recent observations relative to poliomyelitis complicating gestation, and conclude that the risk to the fetus in maternal poliomyelitis is, as in German measles, high if the disease occurs in the first three months of pregnancy and less in later months. It is not clear, however, to what extent the hazard to the fetus is the result of paralysis in the mother. Conte, McCammon, and Christie³ have tentatively exonerated epidemic encephalitis, although not denying the possibility that it, too, may act as a teratogen.

Although not a virus disease, scarlet fever concurrent with pregnancy has occasionally been followed by developmental defects, such as congenital obliteration of the bile ducts in the case reported by Swan and Tostevin.⁶

SUMMARY

A case of multiple congenital defects following maternal varicella is reported. Present opinion on the pathogenesis of anomalies associated with maternal prenatal virus infection is reviewed. The possible teratogenic propensities of maternal virus diseases occurring early in pregnancy are emphasized.

kg in infancy may lead to negative nitrogen balances, levels above those recommended are wasteful since there are no body depots for reserve protein, absorbed amino acids in excess of the needs for growth and maintenance entering interchangeably with fat and carbohydrate into the energy exchange. With further deceleration in the growth curve with increasing age beyond infancy, lower levels of dietary protein per unit of body weight are required for nitrogen retention and protein deposition. The bulk of available evidence indicates that these recommendations [National Research Council allowances] are compatible with normal qualitative and quantitative nutrition as judged by the various means available.

It is generally agreed that if the appetite is normal, approximately 11 to 15 per cent of the calories of the diet should be provided by suitable protein foods at all ages, but a higher percentage may be required under special circumstances. Leitch and Duckworth,²⁸ who have reviewed this subject thoroughly, recommended allowances that are slightly higher at certain ages but in general are in substantial agreement with those of the Food and Nutrition Board. Youmans²⁹ makes similar recommendations.

Estimates of the actual amount of protein required by the infant and child at successive ages to provide for optimum growth tend to overlook several important considerations. Protein will be used first to meet the energy need, if this is not fully met from other sources. If the caloric intake is only moderately below the energy need and if reserve sources of calories have been exhausted, the drain on the protein intake for this purpose may be relatively great. Protein will next be used primarily for repair or maintenance, although some growth will undoubtedly take place at the expense of full maintenance and possibly also through the sacrifice of protein-rich body tissues. Only after these needs have been met will protein provide fully for the enlargement of such tissues as muscle. The points that should be stressed, therefore, in the protein requirements of children are that protein intake cannot be considered adequate unless caloric requirement is met, and that the first and most frequent effect of protein deficit is the limitation of growth. The effect of inadequate protein on growth is not easily recognized, and if correction of diet is not made until faulty growth is obvious or until other signs of deficiency are manifest, the child's progress often will have been considerably interfered with. Since it is not known how much constitutes adequacy for any given child at a particular time, a liberal margin of safety must be provided in the amount and quality of protein foods offered, together with an adequate caloric intake, and an otherwise well balanced diet, so that periods of interference with growth due to lack of protein can be avoided.

Youmans²⁹ has emphasized the importance of acute febrile illnesses as precipitating factors in manifest deficiency states. Infection increases caloric requirements, causes rapid catabolism with nitrogen loss and interferes with normal consumption and utilization of calories and protein, and children are subject to more such illnesses than adults.

Furthermore, the emotional disturbances often affecting both mother and child as a result of the latter's illness, often have profound effects on the child's eating habits and attitudes toward food and hence on food consumption. Youmans's contention applies with special force to childhood when he states that protein requirements are greatly increased by most illnesses and that failure to meet these increased needs by careful dietary planning in illness

TABLE 2 *Recommended Daily Allowances for Protein Expanded for the Growing Period*

Subjects	Age	PROTEIN PER KILOGRAM OF BODY WEIGHT
		gm
Premature infants	1 week to 1 month	6.0-4.4
Premature infants	1 to 3 months	4.4-3.3
Full-term infants	2 days to 3 months	4.4-3.3
All infants	4 months to 1 year	4.0-3.0
Toddlers	1 through 3 years	4.2-2.9
Preschool children	4 through 6 years	3.3-2.5
School children	7 through 9 years	2.6-2.1
School children	10 through 12 years	2.2-1.8
Youths female	13 through 15 years	1.8-1.5
Youths male	13 through 15 years	2.0-1.7
Youths female	16 through 20 years	1.6-1.4
Youths male	16 through 20 years	2.1-1.7

leads to a major number of protein deficiency states. It is difficult and often impossible to maintain nitrogen equilibrium throughout the course of many illnesses, and it is therefore of practical value to provide for storage of nitrogen during convalescence to an amount sufficient to replace damaged tissues and to afford the accelerated growth that usually follows periods of interrupted growth.

Effects of Protein Deficiency

It must be pointed out again that protein is rarely, if ever, the sole nutrient that is inadequate in a diet over any long period. The amounts of other essentials present have much to do with the effects of the protein level itself, and growth is known to be interfered with when various dietary essentials are sufficiently restricted. Except in animal experiments, one can rarely assume that poor growth has resulted solely or even primarily from a quantitative inadequacy of protein. There is a great deal of evidence, however, that low protein usually associated with low calories and continued over long periods is a frequent cause of poor growth in childhood. This evidence is derived in part from animal experimentation, in part from studies of the growth of children in tribal or national groups having different dietary habits, in small part from controlled studies of dietary supplements and restrictions, in part from combined dietary and growth studies of groups of children over long periods and more recently from studies of children subjected to inadequate diets as a result of war restrictions. This evidence is still far from complete, but a characteristic picture of the chronically underfed child, particularly regarding calories and protein, is beginning to emerge from it. Space does not permit a thorough review of these

protein A great body of evidence has been obtained in experience with infant and child feeding that testifies particularly to the unique value of milk proteins but also to the better growth attained on diets liberally provided with milk and other foods from animal sources. These furnish the essential amino acids in suitable proportions and liberal amounts. Nevertheless, Levine concludes, on the basis of evidence from studies on dogs, infants and adults, that positive nitrogen balances of similar magnitude result from equivalent intakes of protein, irrespective of the source of the dietary nitrogen if the protein offered provides all the essential amino acids in adequate amounts.

The quantitative requirements for protein at various ages prior to maturity are increased by an amount necessary to provide for the construction of new tissues laid down in the process of growth. One may arrive at an estimate of the protein requirements for growth in a variety of ways. Nitrogen balance studies on normal subjects, if conducted for sufficient periods, are indicative of the amounts of nitrogen being used for growth. One may also measure the amount of growth and from it estimate the amount of protein required to provide such a gain, but this involves a knowledge of the composition of growth. Since muscle tissue requires the highest deposition of nitrogen and since urinary creatinine excretion is a measure of the gain in muscle tissue, determinations of urinary creatinine excretion are useful in this connection. Clinical studies of growth under known dietary intakes are also useful but must be conducted over long periods and with precise methods both of dietary analyses and of measurements of growth. They throw light on the actual levels of habitual protein intake on which various levels of growth progress may be attained.

The amount of protein necessary to build the new tissues added with growth in any year is a relatively small proportion of the total protein needs when estimated on a daily-intake basis. This assumes that the protein is provided regularly in an otherwise adequate diet so that it is always available for growth. Talbot²⁷ has recently discussed the theoretical basis for this need and has called attention to the remarkably small daily positive nitrogen balance required to yield a significant growth of protoplasm in the course of a year.

Levine²⁸ states that, during infancy, the absolute retentions of dietary protein at equivalent and adequate intakes decline from 0.30 gm of nitrogen per kilogram of body weight daily in the premature infant to 0.15 gm at five months or older. As pointed out above, recommendations for protein allowances are usually expressed in terms of unit of body mass, — either kilograms or pounds of body weight, — but on this basis the need is influenced to some extent by size and consequently by age. It must not be assumed, therefore, that the difference

between the amount recommended on this basis for an infant and that for an adult is entirely due to the rapid growth of the former.

Estimates of protein needs based on theoretical considerations, animal experiments and studies of nitrogen balance, growth and diets in children lead to conflicting conclusions. They have thus far failed to give a clear picture of what the protein requirements are at succeeding ages for optimum growth and health. This is understandable for various reasons. In the first place, it is not known what constitutes optimum growth at any age or for any person. Furthermore, growth in the human being is a slow process, extending over two decades, and children cannot be kept on strictly controlled or known intakes over sufficiently long periods to allow accurate appraisal of growth. Gain in weight is not determined solely by growth, and gain in body length is not a true index of the amount of new tissues laid down.

Human growth progresses continuously from the embryonic period to full physical maturity, but by no means at the same rate at all periods or in equal proportions in different tissues. The protein required for the construction of some tissues is greater than that for others, muscle tissue creating the heaviest demand, and the new tissue components of a young person cannot be analyzed. There are two major cycles of over-all growth separated by a long interval of considerably slower growth. The rapid phase of early infant growth is accompanied by relatively large accumulations of fat in the subcutaneous tissues. The second phase of rapid growth is accompanied by a greater proportionate increase in muscle tissue. Although these changes with time are characteristic of human growth and persons differ only in their magnitudes and their rates of progress, individual differences in all these aspects are so great that variations in protein requirements must be considerable.

The recommendations of the Food and Nutrition Board⁹ may be considered to be as satisfactory guides to protein allowances for infants and children as are available at the present time. They must be recognized as applying only to average normal children within the broad age groups specified. Levine²⁸ has expanded these recommendations to deal more adequately with the subdivisions of the age groups with which they deal. His revised allowances are given in abbreviated form in Table 2. According to these recommendations, the full-term infant under one year of age should be provided a diminishing amount of protein varying from 4.4 to 3.0 gm per kilogram of body weight. Levine makes the following statement:

Analysis of available data for infants under one year establishes that these recommended daily allowances of protein are compatible with a normal rate of total weight gain and a ratio of nitrogen retained to total increment of gain which approximates the rising nitrogen content of the body. Protein intakes below 2.2 gm per

I spent some time during World War II attempting to collect evidence on these effects in studies of children in France, where, as elsewhere, a primary difficulty was lack of precise prewar standards with which to compare war and postwar children. Certain differences found in 1941 between French and American children⁴⁷ may well have resulted from this type of dietary, but it could not be said at the time that they were not national characteristics. After following a small group of the same children in Marseilles over a period of two or three years, Kuhlmann⁴⁸ found that as a group they failed to progress in weight and height to the amount expected for age. Although the numbers successfully followed were too small to give these results convincing significance, in approximately half the children studied growth was moderately but definitely retarded on the basis of normal expectancy and the average increment was approximately two thirds of expectancy.

Osseous development cannot be measured with sufficient precision to determine whether, in a given year or two, a group of children have fallen behind to a measurable degree, but it is of interest that in children studied in France in 1942 osseous development was, on an age basis, retarded in comparison with American standards to approximately the same relative extent as body size.⁴⁹

Another striking characteristic of the children in France and other countries suffering from war restrictions has been their lassitude and inactivity. This physical inactivity tends to spare calories and may conserve protein for structural purposes and appears to be another manifestation of natural adaptation. Diminished activity in childhood causes failure of normal muscle growth, complete inactivity leading to rapid muscle atrophy. It may be said with reasonable certainty that one of the major characteristics of chronic undernutrition in childhood is poor muscular development, and this has been one of the most striking features of the children seen in war-devastated or famine countries. This poor growth of muscle may be attributed to the lack of sufficient protein in the presence of inadequate calories or to lack of activity or, as seems likeliest, to a combination of these.

Keys,⁵⁰ in controlled experiments on conscientious objectors during the recent war, provided diets typical of those in the countries severely affected by the war. He found that most of the weight loss occurring during semi-starvation was due to the loss of muscle tissue. Other striking physical effects were progressive weakness and fatigue. In examining children in France I was impressed with the number who had reasonable amounts of subcutaneous tissue and hence appeared superficially to be well nourished and yet had extremely small and flabby muscles. This suggests that with loss of weight there is some initial loss of subcutaneous fat, but that after this has progressed to a certain but variable degree, further loss is primarily in muscle.

The children with poorly developed muscles were frequently found also to have rather spindly bones, and both linear growth of bones and osseous development appeared to be retarded. Owing to a lack of suitable prewar norms for comparison, however, this cannot definitely be stated to be a result of war. The question of an associated calcium factor enters into the picture. Protein and calcium are both liberally used in the construction of new bone. McCance⁵¹ has shown that calcium absorption is far more satisfactory when a high-protein diet is taken than when protein intake is low. Although the children in France received little milk and rarely any vitamin D supplement, clear evidence of rickets or poor calcium deposition in the skeleton was rarely seen after infancy, but the bones of these children frequently showed lines of interrupted growth. It may be that the poor bone growth observed in France was in part due to unsatisfactory amounts of vitamin D and calcium. It is probable, however, that it was also due to some extent to lack of protein, aggravated by the inadequate provision of calories.

Each of these studies may be considered a piece in a picture puzzle that is as yet far from complete. The general outline that is beginning to emerge, however, reveals that poor growth and development — particularly faulty muscle development and general lack of physical fitness — are frequent consequences of chronic low-calorie, low-protein nutrition in childhood.

I am greatly indebted to Mrs Bertha S. Burke for assistance in the preparation of this review.

studies, but examples of each are cited, nor does it permit a discussion of the possible mechanisms involved in this slowing of growth when structural food substances are inadequate. The growth impulse is apparently so strong that children continue to grow in height and other skeletal dimensions while losing both fat and muscle. Various adaptations, however, sooner or later appear, and these have been more fully considered by Mitchell.⁴¹ Possibly, in the presence of undernutrition, the anterior portion of the pituitary body reduces its excretion of the growth hormone and thus lessens the need for protein by slowing the speed of growth. Other glands may then be affected, and osseous development and the genital changes associated with pubescence may be delayed. There is some evidence that these results actually do occur.

A number of classic studies in the literature show the effect of differences in dietary habits of different tribes on growth and health. The predominant differences in the diets of these physically different tribes were in the quantities of milk, meat and other animal foods consumed. Hence, the major, if not the principal, variants in them would be in the quality and quantity of the protein provided. The studies of Orr and Gilks¹⁵ referred to above offer a striking example. Two South African tribes living side by side under the same climate and with the same agricultural possibilities were chosen for study because they differed strikingly in size and vigor. The larger and more vigorous was a pastoral tribe and lived mainly on milk, meat and freshly drawn blood, whereas the smaller and less vigorous subsisted for the most part on cereals, roots and legumes. The children of the latter tribe were not only smaller than those of the former but were also much more subject to skeletal and dental defects and generally more poorly developed.

The studies of McCarrison⁴² on three tribes in India dealt with one tribe characterized by magnificent physique, unusual fertility and long life, and with two contrasting tribes in these respects. The superior tribe customarily took a simple diet of natural foodstuffs high in all the dietary essentials, the other tribes taking diets low in many of the essentials and obtained largely from plant sources. McCarrison's⁴³ findings on animals fed the same diets were even more striking. It is interesting that Mullick⁴⁴ recently repeated in India McCarrison's classic experiment on rats, with essentially the same results.

The well recognized fact that children of foreign nationals, such as the Japanese, born and brought up in this country are larger than their cousins who continue to live in their country of origin is further evidence along this line, in view of the associated differences in their diets under the changed circumstances.

The many studies of this type are in general agreement that, although heredity plays an important part, other influences are operative in determining

racial and national differences in physique and that diet probably plays a definite part. The principal dietary difference as related to growth and development in childhood seems to be in the consumption of milk and other animal foods, and hence in the quality and quantity of protein. The evidence is quite striking that this characteristic of diet is a major factor in determining the degree of muscular development and the general level of physical robustness, energy and health of a people.

The literature dealing with diet supplements in relation to growth and health during childhood appears to be contradictory and confusing. Kruse⁴⁵ has considered the factors involved that make this understandable and has presented a comprehensive bibliography. Obviously, when the diets of a group of children are adequate to provide for all needs, benefits will not be demonstrable from supplements, and the effect obtained in a given case will depend on the general level of deficiency in the basal diets of the groups studied. On the other hand, when diets are grossly and generally inadequate, almost any supplement will usually show some results.

Of the many studies of this sort, applied principally to school children, the classic experiment of Mann⁴⁶ in England is still outstanding. Two hundred boys six to ten years of age were studied over a four-year period. The children given a pint of milk daily in addition to the basic diet, which was taken by them and by the control group and which contained some milk, gained in weight and height considerably more than the children not given the milk supplement. They were also considered to be markedly improved in general fitness and in health. Subsequently, a number of well controlled studies led to substantially the same results.

The characteristic changes in the diets of large populations of children in Europe due to famine conditions associated with the recent war have been a general lowering of food intake, without characteristic or special lack of any one specific essential. This is in sharp contrast to the changes during World War I, because of increased knowledge of nutrition and better planning and rationing. A sharp increase in the incidence and severity of rickets in childhood was a principal effect of World War I in Europe, but this was not a prominent result of the later war. The major inadequacies in the diets of children have been in total calories and total protein and in the percentage of protein from animal sources. This combination of deficiencies is well suited to bring out the effects of protein inadequacy on growth, but it does not lead to many cases of specific deficiency diseases. The effects on growth have been said to be hard to recognize because they are insidious and cannot be measured without careful observations before and following the periods of food shortages. The customary brief sampling survey usually fails to detect them or at least to measure them.

DR. SCHATZKI This is not an artefact. It may be the edge of the left lung, but it seems to be far over.

DR. ADAMS The edge seems to be clearly outlined.

DR. SCHATZKI Anteriorly, and I suppose that this is the posterior edge of the lung.

DR. ADAMS A final question. Is the apparent defect in the ribs overlying air in the lung rather than disease in the bone?

DR. SCHATZKI I would say that it is not a defect in the rib.

DR. ADAMS The history for six and a half years with a proved mediastinal shift indicates a chronic intrathoracic disease. As stated in the record symptoms typical of bronchial irritation were present at the onset. Six weeks before the final admission the patient developed signs of bronchial invasion or ulceration as reflected by the increase in the cough and the appearance of rust-colored sputum. These symptoms were not obstructive in character since there was absence of pain or fever, and the process was not causing inflammation or irritation of the pleural surface or interfering with respiratory function. Pain in lung disease practically always comes from irritation at some point of either the visceral or the parietal pleura. The gain of 30 pounds in weight in two years is almost exclusive of carcinoma, in spite of the classic symptoms of initial slight cough with mucoid sputum, later increasing and accompanied by blood. The recurrent bouts of "tonsillitis" seem to be irrelevant to this problem unless one of those episodes had caused a lung abscess. The subsequent course after the last episode is inconsistent with the supposition of lung abscess. He did not have symptoms for the ensuing year, and when the symptoms appeared, he was afebrile and the sputum was neither foul nor purulent.

The initial physical examination is not helpful except that it excludes the presence of marked bronchial obstruction at that time. The description of the x-ray findings at the first admission mentions an area of consolidation. Whether this abnormality was a mass or an area of pneumonitis, it is impossible to say without seeing the films, which are not available. Also, the consolidated area is described as adjacent to the septum. It might be of importance to know which septum, the major or the minor, but again the information is not at hand. It is impossible to account for collapse of the right middle lobe by a lesion in the posterior part of the right upper lobe except by extrinsic pressure from a mass that would have to arise in the region of the lateral segmental bronchus of the right upper lobe. Presumably, as shown by the slightly elevated temperature and slight leukocytosis, there was some associated pneumonitis with mild obstruction at that time. It was the posterior wall of the right main bronchus that was displaced forward by extrinsic pressure. The posterior wall is the membranous or yielding portion of the bronchus. The upper-lobe orifice is described as being in the center of the area of ex-

trinsic pressure. There was a pathologic process in or invading the upper lobe as proved by blood oozing from the upper-lobe bronchus, and this is the first proof that the hemoptysis was coming from the same region as that in which the mass seemed to be localized. The statement that no tubercle bacilli were found in the sputum is assumed to mean that adequate bacteriologic examination of the sputum was done really to exclude that diagnosis, and we will henceforth leave tuberculosis out of consideration. The passage of a bougie into the middle-lobe bronchus without difficulty demonstrates that the right middle lobe was collapsed by extrinsic pressure rather than by an intrinsic mass.

The patient was discharged without a histologic diagnosis but with the following evidence as a matter of record: he harbored a mass originating in, invading or ulcerating into the lateral bronchus of the right upper lobe, pressing on the posterior wall of the right primary bronchus and causing collapse by extrinsic pressure of the lower lobe. The surgical service did not know the man's trouble, did not think he needed surgical treatment, or were afraid to offer it, or the patient refused to accept it. That there was no lack of confidence is attested by the patient's continued visits to the Out Patient Department. That he was unimpressed by the potentialities in his case is suggested by the failure to keep appointments after four months and his claim of freedom from symptoms for the next six years—he was free of symptoms, that is, except for two episodes of coughing blood-streaked sputum, which were widely separated by intervals of four years and one year previous to the second admission. On readmission, he had symptoms and signs denoting enlargement of the mass to sufficient size to cause obstruction of the bronchi and pulmonary suppuration in the right lung, yet bleeding was minimal, sporadic and not daily as in carcinomatous ulceration.

The physical findings are not helpful. One word is puzzling in the sentence in which it is stated that the breath sounds and tactile fremitus were "negative." Tactile fremitus is present or absent, increased or decreased, but how it is "negative," I do not know. Dr. Mallory kindly showed me a diagram found in the record of the physical findings, which were, in brief, those of an obstructed lung. The other hospital's interpretation of fluid extending to the fifth posterior rib is altered by reading of the heavy-exposure film taken at the Massachusetts General Hospital to an interpretation of obstructive atelectasis of the right lung, and that interpretation seems to be supported by the clinical chart, the high temperature and the signs of infection. There was a secondary anemia consistent with the status of the illness and infection. Penicillin was given with no more effect on the fever than might be anticipated with bronchial obstruction present.

The question, then, is resolved into the nature of this tumor mass in a fifty-one-year-old Lithuanian

EDITH E PARRIS, *Assistant Editor*

CASE 33151

PRESENTATION OF CASE

First admission A forty-five-year-old Lithuanian leather tanner entered the hospital complaining of a chronic cough and blood-streaked sputum

For about six months before admission the patient had had a slight, chronic cough productive of a small amount of white sputum, especially in the morning Five weeks before entry the cough began to increase, and streaks of rust-colored blood began to appear in the sputum There was no pain, fever, weakness, sweating or dyspnea In the two years before admission the weight had risen from 170 to 200 pounds

For many years recurrent bouts of "tonsillitis" had caused occasional severe sore throat The last of these had occurred a year and a half before admission, at which time the tonsil "broke," discharging blood and pus

On admission the only abnormal physical findings were generalized rhonchi that decreased after coughing and expectoration An x-ray film demonstrated a round area of consolidation in the posterior aspect of the right upper lobe adjacent to the septum, measuring about 5 cm in the transverse diameter The right middle lobe was collapsed On the second day the temperature was 100°F, but afterwards it remained between 98 and 99°F The white-cell count was 12,000, with 76 per cent neutrophils

At bronchoscopy the posterior wall of the right main bronchus was displaced forward by extrinsic pressure The upper-lobe orifice was in the center of the area of extrinsic pressure Blood oozed from the upper-lobe bronchus, and the middle orifice was reddened No tubercle bacilli were found in the sputum A bougie passed into the middle-lobe bronchus without difficulty The lower bronchi were normal At the end of a week the patient was discharged to be followed in the Out Patient Department

Final admission (six years later) In the four months following discharge the patient was seen several times with no change in his status He failed to keep succeeding appointments and was not seen until six years later, when he was referred from another hospital because of fluid in the right side of the chest He claimed to have been free of symptoms, except for two brief episodes of coughing

blood-streaked sputum These occurred, respectively, four years and one year before readmission, and each lasted about a day Six weeks before admission a mild productive cough had developed in association with intermittent rusty streaking of the sputum Four weeks later the patient became feverish, had a headache and felt chilly, although he experienced no frank chill At the other hospital x-ray studies showed "a right hydrothorax rising to the fifth rib posteriorly" Ten to 15 cc of brownish fluid was removed at each of several thoracenteses Penicillin and sulfadiazine were given with no effect on the temperature, which remained elevated After two weeks, the patient was transferred to the Massachusetts General Hospital

Physical examination disclosed an obese, pale, sweating and feverish patient The right side of the chest up to the apex was completely flat to percussion Bronchial breath sounds were audible over the right upper lobe Breath sounds and tactile fremitus were "negative" over the lower lobe and depressed over the middle The left lung was normal Abdominal, rectal and neurologic examinations revealed no significant abnormalities

The temperature was 103°F, the pulse 90, and the respirations 25 The blood pressure was 114 systolic, 64 diastolic

Examination of the blood showed a red-cell count of 4,400,000, with a hemoglobin of 11 gm per 100 cc, and a white-cell count of 8120, with 67 per cent neutrophils The urine, blood sugar, total protein and nonprotein nitrogen were normal On x-ray examination the right lung appeared dense, with the exception of a small aerated area in the upper right portion of the chest The heart and mediastinum were markedly displaced to the right The left lung was clear

In the hospital the temperature spiked from 103 to 104°F every day Abundant colonies of alpha-hemolytic streptococci grew from the sputum Penicillin was started, with no effect on the fever An operation was performed on the tenth hospital day

DIFFERENTIAL DIAGNOSIS

DR RALPH ADAMS* May we see the x-ray films?

DR RICHARD SCHATZKI All the films that were taken are not here, there are no films from the first admission This film shows the mediastinum displaced to the right and air in the apex of the right lung

DR ADAMS Do you consider this area of density to be bony in character?

DR SCHATZKI It looks like it

DR ADAMS Also, on the film the manubrium is outlined, and the trachea is displaced to the right One can postulate a shadow in this region of the tracheal bifurcation that was not mentioned in the record Is that actually something, or is it again an artefact?

*Surgeon Lahey Clinic

ANATOMICAL DIAGNOSIS

Basal-cell papilloma of bronchus, with cornification

PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY The bronchoscopic biopsy from this patient gave the laboratory a difficult problem because it was unlike any bronchiogenic tumor we had ever seen or, so far as I know, any that has heretofore been reported. It was obviously epithelial and contained foci of squamous cells and yet did not look like a squamous-cell carcinoma. After struggling several days with it, we finally returned a diagnosis of basal-cell carcinoma with foci of cornification. Our hesitation was largely based on our belief that so-called "basal-cell carcinomas" are actually tumors of the skin

FIGURE 1

appendages and, therefore, should not occur in mucous membranes. In the registry of lung tumors, however, I have seen a case that was indistinguishable from a basal-cell carcinoma of the skin.

When the lung was resected a large endobronchial tumor was found that had spread through the branches of the upper-lobe bronchus (Fig. 1). It was attached to the bronchial wall at one point only and elsewhere could be readily shelled out with the gentlest of blunt dissection. We could make out no invasion of the lung tissue.

In the group of bronchial adenomas reported from the Army Institute of Pathology by Holley* the tumors are classified into two types, the usual form, which strongly resembles a carcinoid of the appendix, and a second glandular or pseudoglandular type, which sometimes resembles closely the tumors

of the salivary glands that have been described as cylindromas. None of Holley's cases, however, resembled the tumor in the case under discussion, in which the majority of the cells were small, basophilic and slightly spindle shaped (Fig. 2).

FIGURE 2

They were oriented at right angles to the stroma. Occasional cells showed various degrees of cornification. The appearances slightly suggested adamantinoma, and one pathologist who saw the sections was willing to make this diagnosis. I finally called the tumor a basal-cell papilloma with cornification. The regional lymph nodes were free from metastasis, and I believe that the prognosis is good.

CASE 33152

PRESENTATION OF CASE

A forty-three-year-old Italian baker entered the hospital because of jaundice.

Eight weeks before entry the patient had begun to have epigastric discomfort after meals, particularly if the food was fatty or fried. He also complained of fatigue, anorexia and "a heavy head" but continued to work at his job. Six weeks before entry he began to have postprandial nausea. On three occasions he vomited about thirty minutes after

*Holley S. W.—Bronchial adenomas. *Mil. Surgeon* 99:528-554, 1946.

leather tanner—a tumor that started like carcinoma, grew like adenoma and looked like a dermoid. The duration of the manifestations of disease, the long periods of freedom from complaint, the gain in weight and the absence of demonstrable metastases lead one to exclude carcinoma from further consideration in the differential diagnosis. If carcinoma was present in this case, it was only as a degenerative end product in a tumor with a different beginning. If the age and sex of the patient are excluded, this case report is a classic description of bronchial adenoma. Patients with such tumors usually have had symptoms of cough and sporadic hemoptysis for many months when first seen by thoracic consultants. They are in general in good health. The x-ray examination shows signs of bronchial obstruction. In a number of years, even if intraluminal tumors are cleared away, bronchoscopically, extraluminal growth may cause extrinsic pressure leading to obstruction and suppuration and, finally, to resection. Most cases occur in women. Seven out of 8 occur in women under forty years of age. This should be compared with carcinoma, in which 3 out of 4 cases occur in men and in which 5 out of 7 are in patients over forty years of age. The incidence of adenoma is 5 to 10 per cent of that of carcinoma, and five-year cures are obtained in 95 to 100 per cent of cases. The five-year curability rate for resectable carcinoma of the lung is around 7 per cent. Other noncarcinomatous tumors of the lung, such as a hamartoma, myxochondroma and sarcoma, have been seen as solitary examples but have shown no similarity helpful to the differential diagnosis in this case. The lateral and posterior displacement of the trachea, the localized calcification of bony density resembling a canine tooth and the area of surrounding rarefaction, instead of solid density that is expected from a solid tumor, cause one to postulate the presence of a dermoid cyst with rupture into the bronchus as the cause of this man's difficulty and the source of the brownish fluid obtained in quantities of 10 to 15 cc at the other hospital on several occasions. The expectoration of hair or the like, debris, fluid or sputum containing cholesterol crystals or fat droplets, however, was not described in the record. Therefore, I shall have to follow the statistical-likelihood precept of the clinician for whom these exercises are named and make a diagnosis of obstructive bronchiectasis of the right lung caused by bronchial adenoma.

DR DONALD S KING Dr Adams, I think that our bad pennies have returned. This is a case that you and I saw in 1940. Dr Schatzki also saw the x-ray films in 1940. I will read the three notes made at that time. Dr Schatzki says, after describing the x-ray films, "I do not believe that this is an abscess. The localized area of collapse in the upper lobe is most probably due to bronchiogenic tumor. This is the likeliest diagnosis."

My note reads, "Diagnosis not yet clear. No definite evidence of tumor. There may have been two pulmonary infarcts, one in July and one in August. Would like to see the patient in the Pulmonary Clinic in four weeks."

You saw him in the Pulmonary Clinic, Dr Adams, and wrote, "Patient continues in good health. Only complaint is blood-streaked, brown sputum about every third morning—small amount, not foul. Believe episodes are decreasing. No pain in chest, no loss of weight or appetite. Patient advised and reassured. To return for a repeat x-ray film."

The patient himself wrote, "I cannot make the appointment to have the x-ray film repeated. Have a bad cold. Will be in when my cold is better." That is the last that was heard from him.

I saw him when he came back last fall, and our diagnosis was the same as yours—an adenoma of the bronchus.

DR CARROLL B MILLER The transcribed history stops at the second bronchoscopy. I am sorry that Dr Benedict is not here to describe the operation. He had a trying time with the patient. He found a spongy, easily bleeding mass, which he biopsied. The patient was difficult to handle at that point. A good deal of blood and tumor was aspirated over into the left bronchus. Dr Benedict had enough of a view of the carina and the two bronchi to tell fairly well that this was a tumor mass that had almost completely obstructed the right main bronchus. The preliminary pathological report of the biopsy was carcinoma. The patient was referred for exploration. We fully expected the tumor to be inoperable because of the diagnosis of carcinoma returned by the Pathology Department and because of the time interval between the first admission and the last, when we opened the chest, however, we found that the upper lobe was completely collapsed, as we expected, and the middle and lower lobes moderately collapsed, but there was no fluid in the chest and, curiously enough, the mass surrounding the upper-lobe bronchus was small. It was decided because of the location that it would be necessary to do a pneumonectomy. I cut across the main bronchus and found in my incision in the bronchus a tongue of tumor extending 3 mm beyond the point of incision. I was able to extend the incision and get completely around the tumor and do a pneumonectomy, with division of the right bronchus. On inspecting the specimen afterward, we found that the attachment of this tumor, so far as the bronchus was concerned, was several millimeters distal to my incision, with a thumblike projection extending up into the bronchus.

CLINICAL DIAGNOSIS

Carcinoma of bronchus?

Adenoma, right-stem bronchus?

DR ADAMS'S DIAGNOSIS

Bronchial adenoma, with obstructive bronchiectasis

more favors an obstructive type of jaundice. I would suppose that by that time the phosphatase would have been elevated if it followed the usual rule in obstructive jaundice. The cholesterol was slightly elevated. The serum amylase was normal, and the bilirubin was elevated, as might have been anticipated with complete jaundice of that duration. Thus far, the onset of jaundice after atypical transient right-upper-quadrant pain, with absence of a palpable gall bladder, and the low alkaline phosphatase favor jaundice of intrahepatic origin. On the other hand, the normal prothrombin time, the negative cephalin-flocculation test and the absence of a palpable spleen may be taken as evidence against the jaundice being due to liver damage.

I am disturbed about the symptoms five or six weeks before the patient became jaundiced. It seems to me — and this is not on the basis of experience really — that five weeks of prodromal symptoms before developing jaundice is rather longer than I should have anticipated with an acute hepatitis. Thus, I am still unable to reach any definite conclusions but am nevertheless forced to try to make a diagnosis that I am perfectly sure is not going to be correct.

I believe that this patient did not have primarily intrahepatic disease, the evidence is more against than in favor of that diagnosis. I do not believe that the symptoms were due to gallstones. It is unusual for a patient of forty-three, with complaints of only eight weeks' duration, to have a history suggestive of gallstones so indefinite as this, beginning with slight epigastric distress and itching and going into a period of fatigue, malaise and "a heavy head" and then nausea and vomiting. That is so unlike uncomplicated gallstones that it would be impossible for me to feel confident about making such a diagnosis in this man.

The patient had a duodenal ulcer. I cannot get away from the fact that this lesion was probably in the duodenum, and again I cannot state definitely why I get that impression. It is probably because I do not believe that he had intrahepatic disease or gallstones. I had hoped that Dr Schatzki would show a large crater or something else and that there had been reaction enough around the ulcer to make it possible for jaundice to have been secondary to that.

Carcinoma of the ampulla of Vater, of course, is perfectly possible, but I cannot make this diagnosis nor can I exclude it.

I must leave this case without a satisfactory diagnosis in my own mind and simply say that the patient had an ulcerating lesion in the duodenum, which in some way was responsible for obstruction to the common duct.

DR TRACY B MALLORY: Are there any suggestions or comments? Dr Giddings, would you give the opinion on the ward?

DR W PHILIP GIDDINGS: We thought definitely that this man had complete obstructive jaundice, as Dr McKittrick has deduced. We also were rather puzzled regarding the pain and the exact nature of the obstruction. The patient had two conditions — complete obstructive jaundice and blood in the stools — that we tried to add up to a carcinoma of the ampulla. He gave a definite history of pain. There was no palpable gall bladder, however, and there was x-ray evidence of an active duodenal ulcer.

DR MALLORY: Will you give the operative findings?

DR GIDDINGS: We operated with a diagnosis of two diseases: common-duct stone and duodenal ulcer. It was quite apparent that the patient did not have gall-bladder disease. The gall bladder was completely normal, but the common duct was greatly dilated — about the size of a man's thumb. At the lower end of it was a readily palpable tumor. The duct was opened and found to contain crystal-clear white bile, and we could visualize within it a tumor mass that had the appearance of carcinoma. This was biopsied, and adenocarcinoma reported. We did a two-stage Whipple procedure, at the first operation transecting the common duct as high as we could beneath the hepatic artery, and performing a routine type of anastomosis. About three weeks later after recovery from the jaundice, we completed the Whipple type of resection, including the head of the pancreas and the duodenum.

CLINICAL DIAGNOSES

Common-duct stone
Duodenal ulcer

DR MCKITTRICK'S DIAGNOSIS

Ulcerating lesion of duodenum, with secondary obstruction of common duct

ANATOMICAL DIAGNOSIS

Carcinoma of common bile duct

PATHOLOGICAL DISCUSSION

DR MALLORY: The specimen that we were finally provided with consisted of the pyloric end of the stomach, a major part of the duodenum, a segment of the common bile duct and a segment of the head of the pancreas. In the common bile duct slightly posterior to the papilla was a primary carcinoma that had extended into the surrounding tissues. We were completely unable to find any trace of duodenal ulcer. I have no explanation for the discrepancy.

DR SCHATZKI: Was anyone from the X-Ray Department present?

DR MALLORY: I cannot answer that.

DR SCHATZKI: The reason I ask is that we have seen cases in which ulcers have entirely disappeared between the time of examination and either operation or autopsy, I think it is inconceivable that there was no ulcer at the time of examination, although it may have healed by the time of resection.

eating Three weeks before entry, while returning from work at 3 00 a m, he was seized with a severe, colicky, right subcostal pain that occurred in spasms lasting five to ten minutes at a time For the next five hours he had many such spasms associated with restlessness, sweating, chills, weakness and nausea He also had occasional stabs of knifelike pain beneath the left scapula That evening his wife noticed that the eyes were yellow During the next few days he rapidly developed generalized jaundice and itching severe enough to keep him awake at times The urine became dark colored and the stools clay colored Passage of the dark urine was associated with burning The patient also became constipated, moving the bowels only every two to four days Two weeks before entry these symptoms had progressed to the point where the patient had to stop working He saw a physician, who prescribed "pills," bed rest and a fat-free diet Five days before entry he began to have chilly sensations, alternating with sensations of warmth He had had no more attacks of colic, but there was some residual soreness in the right upper quadrant He had lost 15 pounds during the two weeks before entry

The patient's health had previously been excellent except for mild exertional dyspnea and some ankle swelling after long hours on his feet

Physical examination revealed an intensely jaundiced, moderately obese man showing multiple scratch marks of the skin The heart and lungs were normal The liver was firm, smooth and moderately tender Its margin was palpated 7 cm below the costal margin in the midclavicular line The spleen was not palpable

The temperature was 98°F, the pulse 60, and the respirations 20 The blood pressure was 140 systolic, 100 diastolic

Examination of the blood disclosed a red-cell count of 5,280,000, with 12 0 gm of hemoglobin, and a white-cell count of 13,000, with 78 per cent neutrophils The serum phosphorus was 4 4 mg, the nonprotein nitrogen 31 mg, the total protein 7 7 gm, the cholesterol 312 mg, and the cholesterol esters 158 mg per 100 cc, and the alkaline phosphatase 3 8 units and the amylase 12 units per 100 cc The van den Bergh reaction was 14 4 mg per 100 cc direct, and 19 0 mg total, and a cephalin-flocculation test was negative after twenty-four hours and + after forty-eight hours The prothrombin time was normal

The urine gave a + test for albumin and a ++++ test for bile Urobilinogen was present in a dilution of 1 8 The stools were slightly yellow and gave a positive guaiac test Examination of the sediment from duodenal drainage showed absence of bile, the sediment contained numerous red cells and white cells A gastrointestinal series showed a constant deformity of the duodenal cap, in the center of which was an ulcer crater The esophagus,

stomach and lower portions of the duodenum were normal Sigmoidoscopy was negative

The patient was placed on hykinone, atropine and a high-protein, high-carbohydrate, high-vitamin diet

On the eleventh hospital day an operation was performed

DIFFERENTIAL DIAGNOSIS

DR LELAND S MCKITTRICK Before seeing the x-ray films, let us summarize the story The patient stated that eight weeks before admission he had had epigastric discomfort, with some malaise and nausea, and that five weeks later he had had attacks of colicky right-upper-quadrant pain — the pains were apparently colicky because they came in spasms, lasting from five to ten minutes He then began to be restless, had chills and some nausea, and developed jaundice Physical examination on entry did not reveal much, except a liver that was slightly low and moderately tender, and x-ray films showed a presumable duodenal ulcer

DR RICHARD SCHATZKI The films show a definite clover-like deformity of the duodenal cap There is evidence of long-standing duodenal ulcer and probably a crater in the area of maximal constriction I cannot see any abnormality in the second portion of the duodenum

DR ARTHUR W ALLEN How large a crater is that?

DR SCHATZKI I am not sure, as a matter of fact, but I should say about 4 mm

DR MCKITTRICK I cannot put this history together and make it add up to any clear-cut diagnosis Perhaps the thing to do is to take an outstanding symptom, which is jaundice, and see if we can reason from that and get somewhere Was this jaundice, which was obviously not the hemolytic type, due to intrahepatic disease or to obstruction of the external biliary tract?

The patient had pain, but the pain was not sufficiently distinctive to mean much to me The jaundice is somewhat confusing — it was apparently complete At least, the patient had clay-colored stools on admission, and there was no bile in the duodenal contents, I take that statement as being evidence of complete jaundice The liver was slightly enlarged and moderately tender, but that again does not give us too much help The spleen could not be palpated If it had been palpable, I think that we could take that as evidence of a process within the liver, but it could not be felt so that we get no help from that No mention is made of a palpable gall bladder — evidence that would permit the assumption that the process was in the extra-biliary tree

The laboratory evidence is slightly confusing I do not know just how frequently a normal alkaline phosphatase is found with obstructive jaundice Certainly an alkaline phosphatase of 15 units or

by some to result in unconsciousness. This drug produces in conscious patients progressive weakness of the eyelids and strabismus with diplopia, followed by weakness of the throat and jaw muscles and the muscles of the extremities and trunk. Overdosage causes complete respiratory paralysis. The last may be a terrifying experience, and the drug should therefore not be used except in combination with a general anesthetic.

In anesthetic practice, curare may be combined with any of the general anesthetic agents, such as nitrous oxide, ethylene and cyclopropane. If it is used with ether or Pentothal, both of which have a curariform action, the dose should be much smaller than when it is combined with the other agents.

If adequate respiratory exchange is maintained, this drug is apparently quite safe. The greatest danger lies in respiratory depression or even respiratory paralysis from overdosage. Curare should never be administered without adequate facilities for maintaining a patent airway and administering artificial respiration. It has been shown that it takes twenty times as much of this drug to kill dogs when artificial respiration is employed as when it is not. Curare is eliminated quite rapidly from the body. Most of it is broken down in the liver, and the remainder is excreted unchanged by the kidneys.

The pharmacologic antidote for curare is prostigmine. It must be remembered, however, that prostigmine must never be given in lieu of the establishment of a patent airway and the administration of artificial respiration, preferably with oxygen. If adequate respiratory exchange and a sufficient supply of oxygen are maintained, the use of prostigmine should never be necessary. Sufficient recovery of the muscles of respiration to carry on adequate respiratory exchange usually takes place within ten to fifteen minutes.

Abdominal relaxation under curare combined with a general anesthetic approaches that obtained with spinal anesthesia, most surgeons, however, believe that actual operating conditions in the abdomen may not be quite so satisfactory as those under spinal anesthesia. Contraction of the bowel, which is evident under spinal anesthesia, is not usually present when a combination of curare and a general anesthetic is employed.

This drug is unquestionably firmly established as an important addition to the already formidable group of anesthetic agents, and when used by anesthesiologists familiar with its advantages and yet acutely aware of its limitations, it can be a valuable aid to modern surgery. Observations regarding its use in two series of patients appear elsewhere in this issue of the *Journal*.

THE INSTITUTE OF SOCIAL MEDICINE AT OXFORD

It is noteworthy that through the war-torn years in England plans were pursued for the development of an institution at Oxford University that has many potentialities for the betterment of social welfare. The Institute of Social Medicine came into being on April 1, 1943, when John A. Ryle was appointed the first professor of social medicine and subsequently director of the Institute.

By "social medicine" is meant neither schemes for socializing medicine nor medical social work, it is defined in the following stated purposes of the Institute:

To investigate the influence of social, genetic, environmental and domestic factors on the incidence of human disease and disability.

To seek and promote measures, other than those usually employed in the practice of remedial medicine, for the protection of the individual and of the community against such forces as interfere with the full development and maintenance of man's mental and physical capacity.

If required by the University to do so, to make provision in the Institute for the instruction in social medicine of students and practitioners of medicine approved by the Board of the Faculty of Medicine in the University of Oxford.

Thus, the three principles of any great medical institution are incorporated in these purposes: research, medical care and the prevention of disease, and teaching.

The early years of the Institute have had to do with the organization of a number of worth-while projects. An investigation has been undertaken to study the development, health and sickness ex-

CURARE

THERE is something spectacular about the introduction of a new drug that immediately achieves for itself a wide field of usefulness. Only slightly less spectacular is the discovery of a new and widespread use for an old drug, to this category belongs curare.

Curare, the ancient arrow poison of certain South American Indians, has been known for over three hundred years. Sir Walter Raleigh is credited with being the first White man to observe its effects. He apparently became acquainted with it during his famous voyage up the Orinoco in 1595. The ability of curare to effect muscular relaxation and loss of tone by paralysis of the myoneural junction has been known for many years. In fact, no less a person than Claude Bernard established this fact experimentally and suggested the therapeutic use of curare in hydro-

phobia, chorea, tetanus and epilepsy. For many years after his investigations, curare remained essentially a pharmacologic curiosity and a physiologist's tool for the demonstration of the existence of the myoneural junction as a physiologic entity.

To Mr. Richard C. Gill must go the credit for many modern conceptions concerning this drug. Mr. Gill spent a great deal of time in the Amazonian jungles, and it was he who first brought to this country, in 1938, adequate supplies of the drug for accurate assays and standardization. He¹ has recently pointed out that curare is not derived from a single species of plant but is a mixture of botanical components widely distributed throughout both North and South America, more particularly in the region around the Amazon River. McIntyre² and Bennett,³ of the University of Nebraska, were the first to investigate modern curare pharmacologically and to submit it to clinical trial.

Following the investigations of McIntyre and Bennett, curare was first used in the field of psychiatry in an attempt to overcome some of the less desirable side effects of convulsive shock therapy in the treatment of various psychoses. Since the forceful muscle contractions associated with this type of therapy not infrequently resulted in fractures and muscle rupture, it was desirable to have some method of lessening their severity.

Griffith and Johnson,⁴ of Montreal, introduced this drug into the field of anesthesiology in 1942. Their initial report of its use in twenty-five surgical operations was extremely promising. Since that time, many workers in laboratories and clinics have reported favorably on the benefits to be derived by a combination of a general anesthetic, to render the patient insensible to pain, and the intravenous injection of curare, to provide muscular relaxation.

Recent work in the laboratory with this drug has confirmed the statement of Claude Bernard that the primary action was at the myoneural junction. With adequate doses, curare so completely blocks the myoneural junction that the muscles no longer respond either to mechanical stimulation or to the injection of acetylcholine. Curare does not affect nerve conduction.

Curare is not an anesthetic agent or a hypnotic, although the administration of large doses is said

by some to result in unconsciousness. This drug produces in conscious patients progressive weakness of the eyelids and strabismus with diplopia, followed by weakness of the throat and jaw muscles and the muscles of the extremities and trunk. Overdosage causes complete respiratory paralysis. The last may be a terrifying experience, and the drug should therefore not be used except in combination with a general anesthetic.

In anesthetic practice, curare may be combined with any of the general anesthetic agents, such as nitrous oxide, ethylene and cyclopropane. If it is used with ether or Pentothal, both of which have a curariform action, the dose should be much smaller than when it is combined with the other agents.

If adequate respiratory exchange is maintained, this drug is apparently quite safe. The greatest danger lies in respiratory depression or even respiratory paralysis from overdosage. Curare should never be administered without adequate facilities for maintaining a patent airway and administering artificial respiration. It has been shown that it takes twenty times as much of this drug to kill dogs when artificial respiration is employed as when it is not. Curare is eliminated quite rapidly from the body. Most of it is broken down in the liver, and the remainder is excreted unchanged by the kidneys.

The pharmacologic antidote for curare is prostigmine. It must be remembered, however, that prostigmine must never be given in lieu of the establishment of a patent airway and the administration of artificial respiration, preferably with oxygen. If adequate respiratory exchange and a sufficient supply of oxygen are maintained, the use of prostigmine should never be necessary. Sufficient recovery of the muscles of respiration to carry on adequate respiratory exchange usually takes place within ten to fifteen minutes.

Abdominal relaxation under curare combined with a general anesthetic approaches that obtained with spinal anesthesia, most surgeons, however, believe that actual operating conditions in the abdomen may not be quite so satisfactory as those under spinal anesthesia. Contraction of the bowel, which is evident under spinal anesthesia, is not usually present when a combination of curare and a general anesthetic is employed.

This drug is unquestionably firmly established as an important addition to the already formidable group of anesthetic agents, and when used by anesthesiologists familiar with its advantages and yet acutely aware of its limitations, it can be a valuable aid to modern surgery. Observations regarding its use in two series of patients appear elsewhere in this issue of the *Journal*.

THE INSTITUTE OF SOCIAL MEDICINE AT OXFORD

It is noteworthy that through the war-torn years in England plans were pursued for the development of an institution at Oxford University that has many potentialities for the betterment of social welfare. The Institute of Social Medicine came into being on April 1, 1945, when John A. Ryke was appointed the first professor of social medicine and subsequently director of the Institute.

By "social medicine" is meant neither schemes for socializing medicine nor medical social work; it is defined in the following stated purposes of the Institute:

To investigate the influence of social, genetic, environmental and domestic factors on the incidence of human disease and disability.

To seek and promote measures, other than those usually employed in the practice of remedial medicine, for the protection of the individual and of the community against such forces as interfere with the full development and maintenance of man's mental and physical capacity.

If required by the University to do so, to make provision in the Institute for the instruction in social medicine of students and practitioners of medicine approved by the Board of the Faculty of Medicine in the University of Oxford.

Thus, the three principles of any great medical institution are incorporated in these purposes: research, medical care and the prevention of disease and teaching.

The early years of the Institute have had to do with the organization of a number of worthwhile projects. An investigation has been undertaken to study the development, health and sickness ex-

perience of a relatively large group of children up to the age of five. In collaboration with local factories, the Institute is investigating occupational morbidity to sickness and industrial hazards. A survey of how thyroid enlargement in school children is related to the iodine content of drinking water is being carried out extensively in several districts of England and Scotland. X-ray studies of growth and development of bone are being made. In connection with human genetic studies, a pilot survey of forty-two sets of twins of school age has been completed. Statistical analyses of stillbirth rates and neonatal death rates in certain counties and county boroughs are being made. Other activities have included problems in connection with confinement among women of the working class, health examinations, consultative work and the teaching of students in their clinical years at Radcliffe Infirmary. Perusal of the *First Annual Report*¹ suggests that the Institute is attempting to fill in the gaps left by governmental public-health methods of collecting and recording health statistics. Surely, if adequate methods of recording illnesses were put into practice, the work of statistical epidemiology would be much simpler than it is at present.

In his report, Professor Ryle speaks of "social pathology" in contrast to "human pathology," defining the former as follows: "The advancement of our knowledge of man in health and disease and the investigation of the social causes of disease." Incorporated in the concept is the study of the healthy state and of the borderland involving disease. It is not difficult to realize that equal knowledge for human welfare will accrue from directing attention to factors having to do with healthy groups, as with those concerned with diseased groups, and that these are appropriately co-operative fields of investigation.

Elsewhere, Professor Ryle² has stated a point of view that deserves repeating again and again:

We are most of us conscious of the fact that medicine during the past quarter of a century has become (inevitably, be it allowed) not merely more specialized but also more technical, and that in the process—for the technicalities are often precise, intricate and time-consuming—the old aetiological interest and humanism of our fathers have tended to take the second place. In the teaching hospitals this can scarcely be disputed. Investigation to the limit, mainly by objective methods and often with

too little said to or done for the patient during or after the tedious process, has been the prevailing trend, especially in the case of the more chronic or seemingly more obscure varieties of disorder and disease. More and more accurate assessments of local pathology, with the help of more and more colleagues and instruments, and less and less intimate understanding of the patient as a whole man or woman with a home and anxieties and economic problems and a past and a future and a job to be held or lost, have become the order of the day. As we direct our students, so in large measure must the outlook and method of each new generation of doctors be determined.

Professor Ryle, who was formerly Regius Professor of Physic at Cambridge University, recently visited Boston, having given an address at the Harvard Medical School on February 24. His remarks centered about the need for a better understanding of normal variations. He sketched some of the methods that the Institute of Social Medicine is employing to attain this result. Those who met and heard Professor Ryle were deeply impressed. His undertaking deserves success, and it is suggested that his institution serve as a model for needed research activities in this country.

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

BIGELOW—Enos H. Bigelow, M.D., of Framingham died March 13. He was in his ninety-second year.

Dr. Bigelow received his degree from Harvard Medical School in 1882. He was a former president of the Massachusetts Medical Society and a former chairman of the Framingham Board of Health.

EMERY—Edward S. Emery, Jr., M.D., of Brookline died March 16. He was in his fifty-fourth year.

Dr. Emery received his degree from Harvard Medical School in 1920. He was an instructor at Harvard Medical School, as well as senior associate in medicine, Peter Ben Brigham Hospital, and medical consultant, Bedford Veterans Hospital. He was a member of the American Society for Clinical Investigation, American Gastro-Enterological Association and International Society for Gastro-Enterology and a fellow of the American Medical Association.

His father, his widow, two sons and a daughter survive.

EWING—Edward H. Ewing, M.D., of Stoughton, died March 8. He was in his seventy-fifth year.

Dr. Ewing received his degree from the College of Physicians and Surgeons, Baltimore, in 1897.

His widow survives.

HAYES—Arthur Warren Hayes, M.D., of Greenfield died March 11. He was in his fifty-sixth year.

Dr. Hayes received his degree from Middlesex University School of Medicine in 1920. He was a member of the New England Roentgen Ray Society, the Radiological Society of North America and the American College of Radiology, and was a fellow of the American Medical Association.

A sister and six brothers survive.

HILLS—Charles E. Hills, M.D., of Natick, died February 23. He was in his seventy-eighth year.
Dr. Hills received his degree from Dartmouth Medical School in 1901. He was a fellow of the American Medical Association.
His widow, a son and three daughters survive.

RYDER—George H. Ryder, M.D., of Quiney, died March 12. He was in his seventy-third year.
Dr. Ryder received his degree from Harvard Medical School in 1899. He was a fellow of the American College of Surgeons and a member of the New England Ophthalmological Society.
His widow and a daughter survive.

MISCELLANY

NOTES

Thirty-one new faculty appointments and seven promotions at the Boston University School of Medicine were recently announced. In the Department of Medicine, John P. Rutagan was promoted to assistant professor, and James W. Culbertson, Edward D. Freis, William L. Hewitt, Dera Kesser and George W. Waring, to instructors. Burton C. Grodberg was promoted from assistant in gynecology to instructor. New appointments were as follows: Stephen Chang, assistant in medicine, Thomas L. Hartman, instructor in medicine, Timothy R. Talbot, Jr., instructor in medicine, Samuel E. Leard, instructor in medicine, William F. Caveness, instructor in medicine, Philip Kramer, assistant in medicine, Robert M. MacDonald, assistant in medicine, Louis Bachrach, assistant in medicine, William E. R. Greer, assistant in medicine, Thomas Perrin, assistant in medicine, Samuel C. Cohen, assistant in medicine, Harold L. Chandler, assistant in medicine, Donald L. John, assistant in medicine, John B. Graham, assistant in surgery, Donald Ravl, assistant in surgery, David Jennison, assistant in surgery, Robert Bolduc, assistant in surgery, Douglas Farmer, assistant in surgery, Joseph Stanton, assistant in surgery, Richard Lyon, assistant in surgery, John J. Byrne, instructor in surgery, Harry Goldman, instructor in radiology, Paul Massick, assistant in radiology, Harry Lerner, assistant in radiology, Leslie Bragg, assistant in radiology, Lazarus Secunda, instructor in psychiatry, Herbert I. Harris, instructor in psychiatry, Andrew D. Elia, instructor in gynecology, John L. Morrison, assistant in gynecology, John M. McIver, assistant in ophthalmology, and David Stearns, assistant professor of ology.

The following appointments to the teaching staff of Harvard Medical School were recently announced: Albert Burton Anderson, of Cambridge (S.B. Yale University 1932, M.D. Harvard University 1936), assistant in surgery, Henry Philip Breen, of Boston (A.B. Yale University 1937, M.D. Harvard University 1943), assistant in radiology, Johan W. H. Cammermeyer, of Oslo, Norway (M.D. University of Oslo 1940), research fellow in neurology, William Leroy Caton, of Dorchester (S.B. Springfield College 1938, M.D. Washington University 1943), research fellow in obstetrics, Albert I. C. DeFriez, of Cambridge (A.B. Princeton University 1940, M.D. Columbia University 1943), research fellow in physiology, Jane Emerson Denton, of Fort Benning, Georgia (A.B. Wellesley College 1942, M.D. Columbia University 1945), research fellow in anesthesia, Andre de Vries, of Cambridge (M.D. University of Amsterdam 1936), research fellow in medicine, Sydney Saul Gellis, of Newton Centre (A.B. Harvard University 1934, M.D. Harvard University 1938), assistant in pediatrics, Robert Spaulding Hormell, of Melrose (A.B. Harvard University 1935, M.D. Harvard University 1939), assistant in surgery, Evelyn June Lorenzen, of El Reno, Oklahoma (S.B. University of Oklahoma 1942, Ph.D. Cornell University 1946), research fellow in medicine, John Kimberly Meneely, Jr., of Coevmans, New York (S.B. Yale University 1938, M.D. Yale University 1941), assistant in medicine, Dora Gerzenstein Mittelman, of Buenos Aires, Argentina (Ph.D. University of Buenos Aires 1942), research fellow in physical chemistry, Charles Galloupe Mixter, Jr., of Brookline (S.B. Trinity

College 1935, M.D. Harvard University 1939), assistant in surgery, Gordon Steinbach Myers, of Needham (A.B. Harvard University 1936, M.D. Harvard University 1940), assistant in medicine, Eugene Francis Poutasse, of Worcester (S.B. Harvard University 1940, M.D. Harvard University 1943), assistant in surgery, James Alexander Taylor, of Oxford, North Carolina (A.B. University of North Carolina 1939, M.D. Harvard University 1943), assistant in medicine, Alexander Terzin, of Belgrade, Yugoslavia (M.D. University of Zagreb, Yugoslavia, 1939), research fellow in bacteriology and immunology, Suzanne Taets van Amerongen, of Amsterdam, Holland (M.D. University of Amsterdam 1942), assistant in psychiatry, and Pen-Chung Yu, of Kweichow (Kweichow) China (M.B. National Kweichow Medical College 1940), research fellow in bacteriology and immunology.

TREATMENT OF HYPERTHYROIDISM

To the Editor The most important problem in the field of thyroid disease today undoubtedly concerns the proper management of hyperthyroidism. Should a patient with this disease receive medical treatment followed by surgical treatment, or should he receive medical treatment alone? The problem is clear enough and the solution is now perhaps almost as clear.

There is an unfortunate tendency to accept thyroidectomy as an entirely satisfactory method of treatment, and it is true that in the best surgical clinics the operative mortality is extremely low. But the hoarseness of recurrent laryngeal nerve paralysis, the twitch and spasm of tetany and the apathy and lethargy of myxedema are seen with sufficient frequency in patients bearing the mark of the thyroid surgeon to emphasize the fact that the surgical treatment of hyperthyroidism is something less than ideal. Moreover there are patients who continue to exhibit the symptoms and signs of thyrotoxicosis despite one or two operations. Finally, any operation implies a certain amount of danger, discomfort, disability and financial loss. In brief, it is self-evident that any nonsurgical procedure is superior to a surgical one, provided the benefits and the risks are at least equal.

The crucial question, then, is, Have we a safe and effective nonsurgical method for treatment of hyperthyroidism? The answer, I believe, is a vigorous affirmative! In Dr. Frank H. Lahey's paper, "Surgery of the Thyroid Gland," which appeared in the January 9 issue of the *Journal*, he groups propylthiouracil with thiouracil and thioabarbital and repeatedly refers to them collectively as "dangerous drugs." This is an unfortunate and entirely misleading method of discussion. One would not consider gramicidin and penicillin together and refer to them as "dangerous." Each drug requires analysis and classification according to its own merit and its own individual toxicity and propylthiouracil deserves critical evaluation alone, not in the company of its "dangerous" brothers. Propylthiouracil has now been used for nearly two years in several thousand patients. The mortality in the patients receiving the drug is zero. A few minor reactions have been reported, none of which required that the drug be discontinued. No clear case of agranulocytosis has yet been encountered. Undoubtedly more toxic effects will be observed in the future as the use of this chemical increases, but the rate will surely be very small. Except for penicillin it is difficult to name an agent at once so potent and innocuous in the whole field of therapeutics!

Is the drug entirely effective? One must be more cautious in answering this question because the time elapsed since its introduction does not permit a categorical answer. But it appears quite certain that propylthiouracil is effective in reducing the metabolic rate—a controllable "medical thyroidectomy"—within a fairly short period in virtually every patient.

The evidence at hand does not allow a definite statement concerning the problem of remission and recurrence, but there is reason for optimism concerning it. Furthermore there is no reason to suppose that recurrences, when and if they occur, cannot be retreated as safely and effectively as the original condition.

In view of the evidence now available, it seems logical to conclude that in the large majority of patients propyl-

perience of a relatively large group of children up to the age of five. In collaboration with local factories, the Institute is investigating occupational morbidity to sickness and industrial hazards. A survey of how thyroid enlargement in school children is related to the iodine content of drinking water is being carried out extensively in several districts of England and Scotland. X-ray studies of growth and development of bone are being made. In connection with human genetic studies, a pilot survey of forty-two sets of twins of school age has been completed. Statistical analyses of stillbirth rates and neonatal death rates in certain counties and county boroughs are being made. Other activities have included problems in connection with confinement among women of the working class, health examinations, consultative work and the teaching of students in their clinical years at Radcliffe Infirmary. Perusal of the *First Annual Report*¹ suggests that the Institute is attempting to fill in the gaps left by governmental public-health methods of collecting and recording health statistics. Surely, if adequate methods of recording illnesses were put into practice, the work of statistical epidemiology would be much simpler than it is at present.

In his report, Professor Ryle speaks of "social pathology" in contrast to "human pathology," defining the former as follows: "The advancement of our knowledge of man in health and disease and the investigation of the social causes of disease." Incorporated in the concept is the study of the healthy state and of the borderland involving disease. It is not difficult to realize that equal knowledge for human welfare will accrue from directing attention to factors having to do with healthy groups, as with those concerned with diseased groups, and that these are appropriately co-operative fields of investigation.

Elsewhere, Professor Ryle² has stated a point of view that deserves repeating again and again:

We are most of us conscious of the fact that medicine during the past quarter of a century has become (inevitably, be it allowed) not merely more specialized but also more technical, and that in the process—for the technicalities are often precise, intricate and time-consuming—the old aetiological interest and humanism of our fathers have tended to take the second place. In the teaching hospitals this can scarcely be disputed. Investigation to the limit, mainly by objective methods and often with

too little said to or done for the patient during or after the tedious process, has been the prevailing trend, especially in the case of the more chronic or seemingly more obscure varieties of disorder and disease. More and more accurate assessments of local pathology, with the help of more and more colleagues and instruments, and less and less intimate understanding of the patient as a whole man or woman with a home and anxieties and economic problems and a past and a future and a job to be held or lost, have become the order of the day. As we direct our students, so in large measure must the outlook and method of each new generation of doctors be determined.

Professor Ryle, who was formerly Regius Professor of Physic at Cambridge University, recently visited Boston, having given an address at the Harvard Medical School on February 24. His remarks centered about the need for a better understanding of normal variations. He sketched some of the methods that the Institute of Social Medicine is employing to attain this result. Those who met and heard Professor Ryle were deeply impressed. His undertaking deserves success, and it is suggested that his institution serve as a model for needed research activities in this country.

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

BIGELOW—Enos H. Bigelow, M.D., of Framingham, died March 13. He was in his ninety-second year.

Dr. Bigelow received his degree from Harvard Medical School in 1882. He was a former president of the Massachusetts Medical Society and a former chairman of the Framingham Board of Health.

EMERY—Edward S. Emery, Jr., M.D., of Brookline, died March 16. He was in his fifty-fourth year.

Dr. Emery received his degree from Harvard Medical School in 1920. He was an instructor at Harvard Medical School, as well as senior associate in medicine, Peter Bent Brigham Hospital, and medical consultant, Bedford Veterans Hospital. He was a member of the American Society for Clinical Investigation, American Gastro-Enterological Association and International Society for Gastro-Enterology and a fellow of the American Medical Association.

His father, his widow, two sons and a daughter survive.

EWING—Edward H. Ewing, M.D., of Stoughton, died March 8. He was in his seventy-fifth year.

Dr. Ewing received his degree from the College of Physicians and Surgeons, Baltimore, in 1897.

His widow survives.

HAYES—Arthur Warren Hayes, M.D., of Greenfield, died March 11. He was in his fifty-sixth year.

Dr. Hayes received his degree from Middlesex University School of Medicine in 1920. He was a member of the New England Roentgen Ray Society, the Radiological Society of North America and the American College of Radiology, and was a fellow of the American Medical Association.

A sister and six brothers survive.

HILLS—Charles E. Hills, M.D., of Natick, died February 23. He was in his seventy-eighth year.
Dr. Hills received his degree from Dartmouth Medical School in 1901. He was a fellow of the American Medical Association.
His widow, a son and three daughters survive.

RYDER—George H. Ryder, M.D., of Quincy, died March 12. He was in his seventy-third year.
Dr. Ryder received his degree from Harvard Medical School in 1899. He was a fellow of the American College of Surgeons and a member of the New England Ophthalmological Society.
His widow and a daughter survive.

MISCELLANY

NOTES

Thirty-one new faculty appointments and seven promotions at the Boston University School of Medicine were recently announced. In the Department of Medicine, John P. Rattigan was promoted to assistant professor, and James W. Culbertson, Edward D. Freis, William L. Hewitt, Dera Kisev and George W. Waring, to instructors. Burton C. Grodberg was promoted from assistant in gynecology to instructor. New appointments were as follows: Stephen Chang, assistant in medicine, Thomas L. Hartman, instructor in medicine, Timothy R. Talbot, Jr., instructor in medicine, Samuel E. Leard, instructor in medicine, William F. Caveness, instructor in medicine, Philip Kramer, assistant in medicine, Robert M. MacDonald, assistant in medicine, Louis Bachrach, assistant in medicine, William E. R. Greer, assistant in medicine, Thomas Perrin, assistant in medicine, Samuel C. Cohen, assistant in medicine, Harold L. Chandler, assistant in medicine, Donald L. John, assistant in medicine, John B. Graham, assistant in surgery, Donald Rayl, assistant in surgery, David Jennison, assistant in surgery, Robert Bolduc, assistant in surgery, Douglas Farmer, assistant in surgery, Joseph Stanton, assistant in surgery, Richard Lyon, assistant in surgery, John J. Byrne, instructor in surgery, Harry Goldman, instructor in radiology, Paul Massick, assistant in radiology, Harry Lerner, assistant in radiology, Leslie Bragg, assistant in radiology, Lazarus Secunda, instructor in psychiatry, Herbert I. Harris, instructor in psychiatry, Andrew D. Elia, instructor in gynecology, John L. Morrison, assistant in gynecology, John M. McIver, assistant in ophthalmology, and David Stearns, assistant professor of urology.

The following appointments to the teaching staff of Harvard Medical School were recently announced: Albert Burton Anderson, of Cambridge (S.B. Yale University 1932, M.D. Harvard University 1936), assistant in surgery, Henry Philip Breen, of Boston (A.B. Yale University 1937, M.D. Harvard University 1943), assistant in radiology, Johan W. H. Cammermeyer, of Oslo, Norway (M.D. University of Oslo 1940), research fellow in neurology, William Leroy Caton, of Dorchester (S.B. Springhill College 1938, M.D. Washington University 1943), research fellow in obstetrics, Albert I. C. Defriez, of Cambridge (A.B. Princeton University 1940, M.D. Columbia University 1943), research fellow in physiology, Jane Emerson Denton, of Fort Benning, Georgia (A.B. Wellesley College 1942, M.D. Columbia University 1945), research fellow in anesthesia, Andre de Vries, of Cambridge (M.D. University of Amsterdam 1936), research fellow in medicine, Sydney Saul Gellis, of Newton Centre (A.B. Harvard University 1934, M.D. Harvard University 1938), assistant in pediatrics, Robert Spaulding Hormell of Melrose (A.B. Harvard University 1935, M.D. Harvard University 1939), assistant in surgery, Evelyn June Lorenzen, of El Reno, Oklahoma (S.B. University of Oklahoma 1942, Ph.D. Cornell University 1946), research fellow in medicine, John Kimberly Meneely, Jr., of Coeymans, New York (S.B. Yale University 1938, M.D. Yale University 1941), assistant in medicine, Dora Gerzenstein Nittelman, of Buenos Aires, Argentina (Ph.D. University of Buenos Aires 1942), research fellow in physical chemistry, Charles Galloupe Mixer, Jr., of Brookline (S.B. Trinity

College 1935, M.D. Harvard University 1939), assistant in surgery, Gordon Steinbach Myers, of Needham (A.B. Harvard University 1936, M.D. Harvard University 1940), assistant in medicine, Eugene Francis Poutasse, of Worcester (S.B. Harvard University 1940, M.D. Harvard University 1943), assistant in surgery, James Alexander Taylor, of Oxford, North Carolina (A.B. University of North Carolina 1939, M.D. Harvard University 1943), assistant in medicine, Alexander Terzun, of Belgrade, Yugoslavia (M.D. University of Zagreb, Yugoslavia, 1939), research fellow in bacteriology and immunology, Suzanne Taets van Anerongen, of Amsterdam, Holland (M.D. University of Amsterdam 1942), assistant in psychiatry, and Pen-Chung Yu, of Kweichow (Kweichow) China (M.B. National Kweichow Medical College 1940), research fellow in bacteriology and immunology.

scrub typhus and psittacosis" is incorrect with reference to Rocky Mountain spotted fever. About 80 per cent of the convalescent sera taken fourteen days or more after the onset of rickettsialpox were positive for Rocky Mountain spotted fever in significant dilutions. In nearly all cases, however, the titer was lower when tested with the heterologous antigen than with the homologous antigen.

Possibly also worth mentioning is the misspelling of my name, both in the text and in the references. The consistent manner in which it is misspelled suggests that it is a matter of firm conviction.

ROBERT J HUEBNER,
S A SURGEON

National Institute of Health
United States Public Health Service
Bethesda 14, Maryland

The information regarding the spleen and complement-fixation tests was obtained from the October, 1946, issue of the *Quarterly Bulletin* of the New York City Department of Health, but the facts as they are given in Dr Huebner's letter are clearly stated in his papers that appeared in November, 1946, issues of *Public Health Reports*. The misspelling of Dr Huebner's name was inexcusable, and for this, due apology is offered. — Ed

BOOK REVIEWS

Six Problems of the Returned Veteran. By Howard Kitching, MD. With a foreword by Ernest R Groves. 12°, cloth, 124 pp. New York: Emerson Books, Incorporated, 1946. \$1.50.

This is another book that deals with the returning veteran. It is short and is essentially a practical book. It restates much that has been said in the press and on the stage about the return of Ulysses after his Odyssey, but it presents the material compactly and in a readable manner. This book is not profound, but it abounds in common sense and emphasizes the obvious and the logical.

A reading of this volume may help to reassure persons with mild anxiety by helping them to realize that the difficulties encountered in sexual adjustments after prolonged absence from home are frequent problems with certain stock angles and well known solutions. If it serves to do even that much, its publication is well worth while. In the hands of an intelligent person, this book may do even more because of its simplicity and inclusiveness. The material is well organized.

Diseases of the Retina. By Herman Elvyn, MD. 8°, cloth, 57 pp., with 170 illustrations. Philadelphia: Blakiston Company, 1946. \$10.00.

All ophthalmologists and internists who have mastered ophthalmoscopic technic will derive much aid and considerable satisfaction from this work, which lists forty-two retinal entities catalogued in the eight sections of the book. The clinical course, complications, hereditary characteristics, pathogenesis and treatment of each entity are discussed. Of the one hundred and seventy illustrations, nineteen are in color. Each section carries its own bibliography, which facilitates reference to the authorities.

The main strength of this work, in the opinion of the reviewer, consists in the careful correlation between the clinical and the pathological aspects of each entity, and in the general clarity of the text.

The book would probably lose little and gain much if the last two sections were omitted, and the thirty-two pages thus released were devoted to the following items: an acceptable discussion of the metabolism of the retina, its dependence on the chorocapillaries, its anatomy, its physical and colloidal chemistry, as well as its photochemistry, its oxidation mechanism, the functioning of its capillaries under the pressure levels prevailing in the eye and the fragility and permeability of its capillaries—the references on Page 6 to the work of Hueck do not tell the whole story, and an attempt to interest and to inform the neurologist and the ophthalmologist who are given one brief paragraph on papilledema on Page 54, no charts of scotomas resulting from the retinal entities and no discussion of toxins or processes that affect the retinal ganglion cells or the papillomacular

Diagnostic Examination of the Eye Step-by-step procedure. By Conrad Berens, MD, and Joshua Zuckerman, MD, C M. 8°, cloth, 711 pp., with 410 illustrations. Philadelphia: J B Lippincott Company, 1946. \$15.00.

This clinical vade mecum, analyzing step by step the proper procedure in handling the eye patient, from the history taking down through the entire examination according to approved modern methods, should be in the hands of every young ophthalmologist when he starts the practice of the specialty. As he acquires experience and judgment, the ophthalmologist will find the short cuts to information essential to proper diagnosis and treatment. The established ophthalmologist will gain a wealth of useful, detailed information from the pages of this systematic and encyclopedic volume. The illustrations are well reproduced, and many are in color.

Music in Medicine. By Sidney Licht, MD. 8°, cloth, 132 pp. Boston: New England Conservatory of Music, 1946. \$3.00.

Physicians are cast in a unique role in modern society. They see many persons who are in need of emotional outlets in addition to treatment of whatever physical disorders they may have. The words of doctors of medicine carry so much suggestive power that it is regrettable that some fail to use this power constructively. Many facilities available for psychologic healing are neglected. Dr Licht believes that music is particularly curative and has a unique and important place in medicine. In support of this opinion, he has gone through the existing literature on this subject and has made in addition many fresh observations of his own. He has organized the material systematically into an interesting volume that emphasizes the deeper psychologic uses as well as the more conventional, superficial advantages that music offers the receptive person. This practical and pleasant book will appeal particularly to physicians and patients who are inclined to make the most of social resources that are close at hand.

Dr Licht writes in an informal and graceful manner. His style is provocative and spontaneous. In this book he shows appreciation of psychologic medicine as well as of music. Many people have used symphony concerts for years as a form of self-administered psychotherapy. With the radio and with music better recorded and more cheaply available than ever before, this book is especially timely.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Surgical Treatment of the Nervous System. Supervising editor: Frederic W. Bancroft, MD, associate clinical professor of surgery, Columbia University College of Physicians and Surgeons, attending surgeon, New York City and Beth David hospitals, consulting surgeon, Veterans Administration, Lincoln and Harlem hospitals, New York City, and Kings Park State Hospital, Kings Park, New York; associate editor: Cobb Pilcher, MD, associate professor of surgery, Vanderbilt University School of Medicine, and visiting surgeon, Vanderbilt University Hospital, Nashville, Tennessee. 4°, cloth, 534 pp., with 293 illustrations and 5 color plates. Philadelphia: J B Lippincott Company, 1946. \$18.00.

Pneumoperitoneum Treatment. By Andrew L. Banyai, MD, associate clinical professor of medicine, Marquette University Medical School. 8°, cloth, 376 pp., with 74 illustrations and 16 tables. St. Louis: C V Mosby Company, 1946. \$6.50.

Neurosis and the Mental Health Services. By C P Blacker, MD, FRCP. With a foreword by Sir Wilson Jameson, KCB, MA, MD, LL D, FRCP, chief medical officer of the Ministry of Health and the Ministry of Education. 8°, cloth, 218 pp., with 56 tables. New York: Oxford University Press, 1946. \$5.00.

thiouracil alone is the method of choice in the treatment of hyperthyroidism

RALEIGH W BAIRD, JR., M.D.

53 Greenough Street
Brookline, Massachusetts

* * *

The above letter in its original form concluded with the sentence, "It seems logical to conclude that thyroidectomy for hyperthyroidism deserves a place in the surgical graveyard, when other outmoded procedures rest in uneasy peace." This was forwarded to Dr Frank H Lahey, who was later informed that Dr Baird had requested that the last sentence be changed to read as printed. Dr Lahey's reply is as follows:

To the Editor Dr Baird's conclusion that subtotal thyroidectomy is outmoded in the treatment of hyperthyroidism since the advent of newer antithyroid drugs seems premature. He admits that the evidence at hand does not allow a definite statement concerning the problem of remission or recurrence on withdrawal of the drug, be it either thiouracil or propylthiouracil. The incidence of prolonged remission after the withdrawal of treatment with these drugs in patients with severe or moderately severe hyperthyroidism has, in our experience, been extremely discouraging. We agree, and have so reported, that these drugs produce remissions in patients with mild hyperthyroidism who have small goiters.

His statement that propylthiouracil can be given without danger is not substantiated by facts. There is even danger in its short-term use, as we have used it. We have observed significant blood changes in 5 of 370 patients treated with propylthiouracil. One was a typical severe case of agranulocytosis, and a fatality was prevented by energetic treatment with penicillin. The danger of development of sensitivity from repeated courses of treatment, should a relapse develop, needs further evaluation, as does the possible danger of grave histopathologic changes following prolonged maintenance treatment.

Since no hope for restoration of the thyroid gland to normal size and structure can be held by virtue of the use of these drugs, it is evident that their action cannot be curative. On the other hand, it has been our experience in a series of 750 cases that either thiouracil or propylthiouracil is entirely effective in returning the basal rate to normal in every case if given in a large enough dose over a sufficient length of time.

The possible dangers of unskillful thyroid surgery have been the basis of numerous papers from this clinic, and we are well aware of such dangers. A blanket condemnation of thyroidectomy as a useful procedure on the basis of these dangers, which can be circumvented, seems to lack logic. Similar condemnation of gall-bladder surgery because of possible injury to bile ducts may be made with this type of reasoning. There are a great many places all over the country where safe thyroid surgery is being done.

We are given the responsibility of restoring to health, in the shortest possible time, approximately 560 hyperthyroid patients each year. As our experience has shown that proper preparation of the patient with antithyroid drugs followed by thyroidectomy offers the best chance of restoration to health with minimal operative risk and morbidity and low recurrence rate, we expect on the basis of present knowledge to continue this type of treatment. This plan of treatment eliminates the uncertainty of cure that is inherent in treatment with antithyroid drugs. We shall continue to give patients with mild hyperthyroidism with small goiters or with recurrences the benefit of a trial with iodine or antithyroid drugs in the hope of inciting a remission.

Boston 15

store, in the garage, post office and hospital and on the street the arm describes the same arc. These people say, "Doctor, right here is the trouble." They get me out of bed in the early morning to tell me about it. When I go to bed at night if I go to bed, they are still telling me about it. They tell me not only about themselves, with the minutest detail, but also about all the other members of their families who have the bug and about all their relatives in Boston or New York or some other place who have been sick. They don't stop there; they go back a generation and tell me how they and their families suffered in 1918.

Three weeks ago a miracle occurred. The telephone hardly rang for two days. Only one or two came to the office. I said to myself, "The epidemic is over. It has been pretty tough, but a doctor has got to go through those things once in a while. Life isn't so bad after all." The sun shone brightly on those two days, the sky was a brilliant blue, and the air was like wine. "I shall relax," I said, "and work on the farm, I shall go to see my friends and gaze at the mountains beyond our valley."

I was never more deluded in my life. On the third day the telephone began to ring again, the office filled up, and the daily grind of getting in and out of a car and reaching for the little black bag was just as it had been. The arm began to describe the same quarter circle. Nothing was different except that the complaints became louder and the response to treatment wasn't so good. They told me about this in no uncertain terms and wanted to know whether I had made a mistake in the medicine and what I was going to do about it.

Two or three weeks ago I ventured out on the street. I never do that any more. I never get out of my car except when I go to the office or am making a call. It is too risky. I can't walk a quarter of a block without someone stopping me and saying, "Doctor, my husband is sick. Won't you drop around and see him?" I regard her with a dead-pan look and say, "What is the matter with him?" — all the time watching for that right arm to begin to move. "He has the flu, I guess." "What is his temperature?" "One hundred and two." "That is nothing," I say, "I should be alarmed if he didn't have a fever, some of them have a temperature of 104 or 105." (This last statement is a slight exaggeration, but there is method in it.) "But Doctor, he has an awful headache." "That is perfectly normal," I say. "They all have awful headaches. It will let up soon." "But Doctor, his cough. I am afraid it will settle on his lungs. He has weak lungs, you know. The trouble seems to be up here now." Then I see the right arm begin to move. I am licked, and after wasting ten minutes in a vain effort to get out of making a call, I go to see him.

So I have given up walking on the streets. I don't go into stores any more. If I have anything to buy, I go to the neighboring town. Sometimes it is absolutely necessary to go to the local drugstore. I slink in, keeping close to the wall, and taking advantage of any cover that presents itself until I reach the prescription desk, where I am safe. When I go out I make a plunge for the door with my head down, like a halfback going through the line.

If there was any milk of human kindness in me, there isn't any now. I am as about as sympathetic as a fish, and I look on the human race with fear and aversion. I never smile any more. I never say anything unless it is absolutely necessary. When someone asks me how I am, I say, "Fine, thank you." I wouldn't ask them how they are for any amount of money. One can't risk the consequences of a question like that.

I have gone into my symptoms and mental state in some detail, because I thought that you would want to know all the facts pertaining to my case.

NEIL C STEVENS

Walpole, New Hampshire

RICKETTSIALPOX

To the Editor The editorial "A New Rickettsial Infection in New York City," which appeared in the January 9 issue of the *Journal* was excellently written and quite informative.

I was particularly interested in the statement that in rickettsialpox the spleen is "palpable in about half the cases." I was aware that in some cases a palpable spleen had been reported, but I have as yet seen no data that could be made the basis for calculating the percentage of palpable spleens that occur in rickettsialpox.

The statement "Complement-fixation tests were negative for typhus fever, Rocky Mountain spotted fever, O fever,

A COMPLICATION OF THE "FLU" EPIDEMIC

To the Editor I have lately begun to show rather alarming symptoms. If the "flu" epidemic continues much longer, I am sure I shall become deranged. If you hear that I am standing on a street corner somewhere describing a quarter of a circle with my right arm and ending with the tip of the index finger an inch below the larynx, you will know the worst has happened. All day long I see nothing but that right arm happen. It is impossible to escape it. In every house and

THE VALUE OF IMPONDERABLES*

REGINALD FITZ, M.D.†

BOSTON

EVERY medical student is familiar with the Ether Dome of the Massachusetts General Hospital and the words beginning, "On October 16, 1846, in this room, then the operating theater of the Hospital, was given the first public demonstration of anesthesia to the extent of producing insensibility to pain during a serious surgical operation." I have often wondered how knowledge of this achievement spread over the world so promptly—largely, it seems to me, through a strange combination of the two imponderables chance and friendship.

Dr William Morton was a dentist, young and ambitious, poor and struggling hard to obtain a foothold in Boston. He was an ingenious person in a region where bad teeth were frequent so that he quickly managed to achieve distinction as a maker of false ones. From his early days he had a flair for publicity, and soon after entering practice he formed the habit of advertising in the newspapers, in this way he grew to be friends with one of the shrewdest reporters—a man named Albert Tenney,‡ of the *Boston Evening Journal*.

The newspapers made interesting reading. In the fall of 1846, besides realizing that Dr Morton could provide a reliable and handsome set of false teeth by a new process, one might have picked up what little needed to be known of the events on the periphery of a universe of which Boston was clearly the hub, in addition to keeping comfortable track of the deaths or other misadventures of one's friends, one might have discovered that early in November the new building of the Harvard Medical School on North Grove Street was to be opened.

The *Boston Evening Journal* came out in the late afternoon and gave the news in a chatty fashion, easy to read while one's head nodded after supper

as one sat by the table in the parlor where the reading lamp was placed. When you got home on Thursday evening, October 1, and glanced through the paper, your fancy, I trust, was caught by the following item:

We would call the attention of our readers to the advertisement of W. T. G. Morton, Dentist, No. 19 Tremont Row. This gentleman has been very successful in his practice in the city. Last evening, as we were informed by a gentleman who witnessed the operation, an ulcerated tooth was extracted from the mouth of an individual, without giving him the slightest pain. He was put into a kind of sleep, by inhaling a preparation, the effect of which lasted for about three-quarters of a minute, just long enough to extract the tooth. The gentleman, who detected the principal ingredient of the preparation by its odor, states that the use of it is entirely free from danger.

You had no way of knowing that here was reported the astonishing adventure that Mr Eben H. Frost had experienced. Nor, unless you had the imagination of Dr Morton, Mr Tenney and young Dr Henry J. Bigelow, did you appreciate, as Dr Waterhouse might have remarked, that here was something curious in the medical line—a painful surgical operation conducted painlessly. Most probably you merely glanced at the paragraph, yawned rather scornfully, and remarked to your wife that Dr Morton was going much too far in his efforts to get patients.

The Saturday, October 17, issue, however, printed something much more startling. Now you read a paragraph that was almost incredible:

Successful Operation. Yesterday morning, Dr Morton, Dentist, No. 19 Tremont Row, at the invitation of Dr Hawwood, visited the McLean Hospital, and administered his preparation to produce sleep, to a person about to undergo the operation of the extraction of a tumor from the neck. We learn from a gentleman who conversed with one of our oldest and most respected physicians who witnessed the operation, that the success of Dr Morton's experiment was complete. The patient sitting in a chair, with every thing made ready by Dr Warren who extracted the tumor, inhaled the preparation for a very brief space of time, when he fell into a quick slumber, and the surgeon proceeded to extract the tumor. The patient did not manifest the slightest symptoms of suffering, and no muscular action whatever. He appeared to be totally insensible to what was going on, till very near the close of the operation, which was quite protracted, when he drew a long sigh. It is quite as much for the in-

NOTICES

CUTTER LECTURE

The Cutter Lecture on Preventive Medicine will be given at 5 p m on Tuesday, April 22, in the Amphitheater of Building D of the Harvard Medical School Dr Thomas M. Rivers, director of the Hospital of the Rockefeller Institute for Medical Research, New York City, will speak on the subject "Certain Public Health Aspects of Infectious Diseases"

The medical profession, medical and public-health students and others interested are cordially invited to attend

BOSTON UNIVERSITY SCHOOL OF MEDICINE ALUMNI ASSOCIATION

The annual alumni meeting and scientific program of Boston University School of Medicine will be held on Friday, May 9

The scientific program will be held in the auditorium of the medical school The lectures will be open to the medical profession

PROGRAM

- 10 00 a m The Treatment of Congestive Heart Failure
Dr Norman H Boyer
- 10 30 a m The Clinical Use of Benadryl and Pyrazinamide Dr Francis C Lowell
- 11 00 a m Newer Concepts in the Management of Asthma Dr John J Curry
- 11 30 a m The Clinical Uses of Folic Acid Dr Joseph F Ross
- 2 00 p m Recent Developments in the Treatment of Peptic Ulcer Dr Franz Ingelfinger
- 2 30 p m The Use of Anesthetic Procedures in Diagnosis and Therapy Dr Julia Arrowood
- 3 00 p m The Management of Acute Renal Insufficiency
Dr Charles Burnett
- 3 30 p m The Problem of the "Sore Throat." Dr Louis Weinstein

The annual meeting and banquet of the Alumni Association will be held at 7 p m in the Georgian Room, Hotel Statler The guest speaker will be Francis W Dahl, well known cartoonist of the *Boston Herald*, whose subject will be "Dahl Looks Things Over" Daniel L Marsh, president of Boston University, will greet the alumni Alex J McFarland, secretary of the Class of 1930 of Dartmouth College, will speak on the subject "Dartmouth Alumni Plan" Dean Donald Anderson, of the medical school, will give a progress report Dr Roger M Burgoyne, president of the Alumni Association, will preside

(Notices continued on page xix)

used it successfully in the extraction of teeth and that he hoped Dr Warren might be willing to try it on a larger scale at the Hospital. Dr Warren finally consented,* and having made up his mind, did much as any of us would do today: he told his house-officer what was in the offing and suggested that he be on the lookout for a suitable case. This must be a patient requiring a relatively minor opera-

a pleasant diversity of talent and age so that conversation developing among them should be interesting. Of the medical men Dr Jackson was perhaps the first scientist of his day — a chemist, physicist, geologist and mineralogist, highly thought of by his contemporaries. Dr Gould was equally unusual, besides being a wise physician, he was well known as a conchologist and zoologist. One can

FIGURE 2 *The First Use in Boston of Ether as an Anesthetic Agent*

tion that should be sufficiently uncomfortable so that relief from pain through the use of Dr Morton's preparation — if this were possible — would be striking. And thereupon he turned his mind to more entertaining matters †

For some time Dr Warren had been considering the formation of a club where new ideas as they came along could be discussed intelligently by a representative group of men. At last he determined to hold a trial meeting of such a prospective organization and therefore invited to his house seven carefully selected friends: Messrs Abbott, Lawrence, Francis C. Gray, Theophilus Parsons, Martin Brimmer and George Darracott and Drs Charles T. Jackson and Augustus Gould. Like Warren himself, they were prominent in their various fields and interested in Boston and progress, and moreover, they included

judge, from its original composition, that the Thursday-Evening Club — as the organization came to be called — proposed to be no flippant affair but that its meetings were to be conducted with all possible seriousness and dignity.

In the meantime, on October 13, Gilbert Abbott, a twenty-year-old printer who had the misfortune of having a tumor on his neck, chanced to enter the hospital. Obviously, an operation would be to his benefit, and his seemed about the type of case that Dr Warren was on the lookout for. The upshot was that Dr Morton received the following letter:

Dear Sir, —

I write at the request of Dr J. C. Warren to invite you to be present on Friday morning, at ten o'clock, to administer to a patient then to be operated on, the preparation which you have invented to diminish the sensibility to pain.

Yours respectfully,

C. F. HAYWOOD

House Surgeon to the Massachusetts General Hospital

*Dr. Morton's advertisement in the *Transcript* for October 11 gives Dr. Warren's name as a reference. This suggests that Dr. Warren may have observed the new method in operation.

†The best accounts of Dr. Warren's part in the introduction of ether are found in the biography of Warren¹ and in his own article.²

terest of the surgeon as for the patient that the preparation should be administered for while it renders the latter insensible to the pain attending severe surgical operations, it affords the former the means of doing his work, freed from all interruptions on the part of the patient, and gives him facilities for performing operations in the most expeditious manner*.

Several apparently fortuitous incidents occurred during the interval between the appearance of these notices. Among others, Mr Tenney engaged in a new enterprise, Dr Bigelow began to explore a new field, and older men of great influence, like Dr Jacob Bigelow, Mr Edward Everett and Dr John C Warren, made their appearance on the scene. Dr Bigelow was president of the Massachusetts Medical Society, Mr Everett was president of Harvard

impressed by Dr Morton's methods that presently he signed an unusual contract† he agreed to study with Morton to master the art of dentistry and in return to be responsible for such advertising and other writing as his chief should direct. He proved an admirable publicity agent, so that in a surprisingly short time more than a hundred persons were able to testify that teeth could be extracted with negligible discomfort.

Young Dr Bigelow was deeply imbued with the numerical method of Louis as applied to clinical research and was bounding with energy and enthusiasm. He had been appointed to the staff of the Massachusetts General Hospital but so far had been given little opportunity to demonstrate his ability

FIGURE 1 The Massachusetts General Hospital in 1846

The Ether Dome can be seen, as well as the new building of the Harvard Medical School, which is in the left foreground

College, and Dr Warren not only was senior surgeon at the Hospital and professor of surgery at Harvard Medical School but also had his finger in almost every pie important to the social and intellectual life of the city.

Mr Tenney, with a good newspaperman's sense of news values, had been present at Dr Morton's office to witness Mr Frost's extraction. He was so

*This is the first printed account giving any details of the operation. Its typographical errors make it all the more interesting. Dr George Hayward was the surgeon on the hospital staff next in seniority to Dr J. C. Warren. Dr Charles F. Heywood was the surgical intern. "The McLean wood" represents a reasonable cross between the two names. "The McLean Hospital" was probably meant to be printed. "the McLean Street Hospital" Mr Tenney probably wrote this note and Dr Gould was probably the respected physician referred to as being present. He lived across the street from Morton and was one of his friends.

When he read of Mr Frost's adventure, he perceived its implications and at once began to investigate it — first, by satisfying himself that Mr Frost had told the truth, and next, by making clinical observations in Dr Morton's office on the manner in which patients behaved after they had been put to sleep by the new process.

Soon the combination of Morton, Tenney and Bigelow was so well established that Morton considered himself justified in calling on Dr Warren. He stated that he believed that a means for preventing pain in surgical operations existed, that he had

†A copy of this contract is in the Boston Medical Library.

This was ether's coming-out party in Boston and the source from which Bostonians began to hear about it in an authoritative way

Dr Jacob Bigelow, besides being president of the Massachusetts Medical Society, was president of the American Academy of Arts and Sciences. The Academy was scheduled to hold a meeting on November 3, when Mr Benjamin Peirce, professor of astronomy at Harvard College, was to say something about a new planet that had been interesting Boston stargazers*. At the last moment he was unable to keep this engagement, and Dr Bigelow was compelled to find a substitute. It seemed natural to fill in with his son, who seemed to have something worth talking about. Unfortunately, there is no account of how his speech was received. The record states simply, "Dr Henry J Bigelow gave some account of a new process of inhalation employed by Dr Morton of Boston, to produce insensibility to pain during the performance of operation by the dentist and the surgeon." Yet the meeting had far-reaching results, it drew the attention of another group of influential people to ether particularly that of Mr Everett.

The new building of Harvard Medical School was to be opened the next day, and as part of the ceremonies Mr Everett had agreed to deliver an address. By way of preparation he admitted that he had done little more than glance over a copy of the history of the school and put together a few notes. When he heard young Bigelow at the Academy, however, he gathered that some sort of stupefying gas prepared by Dr Morton had been used with fair success to prevent pain in two surgical cases, and he was impressed with the youthful speaker's sincerity and ability. Therefore, apparently, he decided to make a graceful and noncommittal allusion to this in his speech, his words concerning the importance of training in relation to medical research are of special interest.

It is not to be expected that discoveries like Jenner's can frequently reward the investigations even of the most sagacious. To exterminate a disease which has desolated mankind for centuries, is of course an achievement not to be often repeated. But discoveries and improvements of all kinds are likely to keep pace with the advance of education in general and professional studies. The greater the number of individuals whose perceptive powers have been awakened and guided by sound studies and wise discipline, the greater the probability that some sharpened glance will penetrate the yet undiscovered mysteries of nature.

A few days later, young Dr Bigelow⁴ read his paper, "Insensibility during Surgical Operations Produced by Inhalation," before the Boston Society for Medical Improvement. This was an amplification of what he had said at the Academy so that one can judge why Mr Everett found his remarks noteworthy. Bigelow told of his experiments with ether, "the odor of which was readily recognized in the

preparation employed by Dr Morton." He reviewed the literature concerning its properties. He described Morton's technic for its administration and the way people reacted when they inhaled it. He stated that its use was clearly adapted to operations that were brief in duration, whatever their severity, he was less certain that it was applicable in operations requiring complete muscular relaxation, such as the reduction of dislocations and the repair of strangulated hernias, conceivably it might prove safe to administer for a long period and to produce prolonged narcotism.

The paper was printed as the leading article in the November 18 issue of the *Boston Medical and Surgical Journal* and was the first published description of the use of ether by any Boston physician.[†] But that particular date is worth remembering for another reason: it was the day on which Mr Everett's daughter developed a toothache. He took her to Dr Morton and described the visit in the following words:[‡]

She was thrown into a state of insensibility by breathing the vapour[§] of ether prepared in some undivulged way. The operation of inhaling the gas lasted about two minutes and the state of unconsciousness as much more. Some loss of time took place in consequence of her jaws being rigidly closed. The operation had to be repeated three times in consequence of the tooth breaking to pieces; and the process of digging out the roots would have been extremely painful if not performed in a state of unconsciousness. No unpleasant consequences of any kind followed the operation.

Mr Everett had been prevailed on to publish the address that he had delivered so offhandedly at the opening of the medical school. He decided to change the final proof, which was still before him, referring to the paragraph on medical research, he added the following footnote:

I am not sure that since these remarks were delivered a discovery has not been announced, which fully realizes the predictions of the text, — I allude to the discovery of a method of producing a state of temporary insensibility to pain, by the inhalation of a prepared vapor. A full account of this discovery is given in a paper, by Dr Henry J Bigelow, in the *Boston Medical and Surgical Journal*, for the 18th of November, 1846. Dr Bigelow ascribes its first suggestion to Dr Charles T Jackson, and its application under his advice, for the purpose of mitigating pain, to Dr W T G Morton, dentist, both of Boston.

I witnessed a very successful instance of the application of the prepared vapor, on the 18th of November, and was informed at that time by Dr Morton, that he had employed it in several hundred cases of dentistry. It has also been made use of with entire success at the Massachusetts General Hospital, and elsewhere in Boston, in capital operations of surgery. The few cases of failure may perhaps be ascribed to irregularities in the process of inhalation, or to peculiarities of temperament or constitution on the part of the patient.

I understand that great confidence is placed in this discovery, by the most distinguished members of the medical

*The *Boston Medical and Surgical Journal* for October 21, 1846 reported "Strange stories are told in the papers of a wonderful preparation in this city by administering which a patient is affected just long enough to undergo a surgical operation without pain." Apparently the editor Dr J V C Smith, took little stock in the early rumo's.

†This episode is described in Mr Everett's diary.

‡The spelling of "vapor" varies. Mr Everett spelt it "vapour" in his diary and "vapor" in his published address. Dr Jacob Bigelow in his letter to Dr Boott also used the former style.

§This information is found in Mr Everett's diary, deposited in the Massachusetts Historical Society.

And on October 16 Dr Warren made the following entry noted in his diary

In the morning went to the Medical College to make some experiments on the renovation of decayed bones

The second operation was performed on the following day and with more striking success. Thus, ether had begun to make a little noise around Boston when the Thursday-Evening Club convened

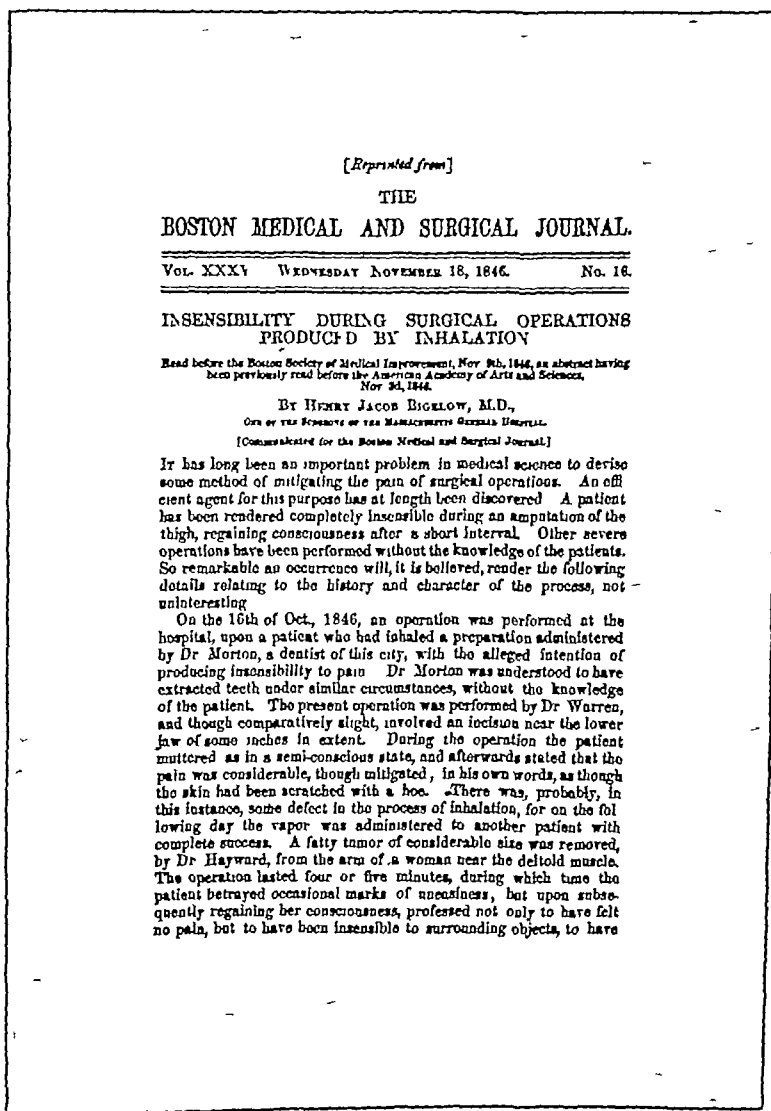

FIGURE 3 Title Page of a Reprint of Dr Henry J Bigelow's Paper

This is the first publication by a Boston physician describing the use of ether. The reprint is a curiosity because it is incomplete, all controversial discussions that appeared in the original paper having been deleted.

with glue. White glue gives, in some cases, a beautiful appearance, and the black gives great strength.

Did an interesting operation at the Hospital this morning, while the patient was under the influence of Dr Morton's preparation to prevent pain. The substance employed was sulphuric ether.*

*Both Dr Warren and Dr Hayward believed that the effect of ether in this case was incomplete; the suffering, however, was less than it would have been under ordinary circumstances, and the result was satisfactory enough to justify further trial. For Dr Hayward's recollection of this occasion see Hayward.²

for the first time on October 27, Dr Warren's record of this momentous occasion was as follows

At this meeting, the application of ether, for the prevention of pain in surgical operations, was first made the subject of discussion between Dr Gould, Dr C T Jackson, and myself, and we then learned from Dr Jackson, that he suggested to Dr Morton the use of ether for the prevention of pain in a patient who was to undergo a severe dental operation.

land by chance, because several isolated and inconsequential events in Boston combined to make many different persons of importance conscious of a great medical event, by friendship, because older men like Dr Jacob Bigelow, Dr Boott, Mr Everett and Dr J C Warren knew and trusted each other and were glad to lend their influence in promoting something of general usefulness that had been originated by younger colleagues

Ether reached France in a similar manner Dr John D Fisher,* an imaginative man who never followed the beaten track, had graduated from Harvard Medical School in 1825 He had gone abroad when he obtained his degree and had studied in Paris under Louis When he returned to Boston to practice, he took an active interest in progressive medicine, thinking especially of people less fortunate than himself He made several useful and original contributions among others, that of auscultation of the skull as a diagnostic method He is known most widely as founder of the Perkins Institution for the Blind Apparently, he did no formal teaching at the medical school, although in contemporary catalogues he is listed as "preceptor" — one of those practitioners who were chosen to be responsible for supervising both the professional studies and the moral characters of students placed in their charge

Francis Willis Fisher,† his nephew, was assigned to him in 1842, young Fisher was a mysterious person about whom little is known beyond the fact that he attended the Boston Latin School, took an active part in the affairs of the Boylston Medical Society as an undergraduate, joined the Massachusetts Medical Society as promptly as he could, and emulated his preceptor on graduation by going to Paris for final polishing

Dr John Fisher had been appointed to the staff of the hospital in 1846 and was interested in ether, he wrote to his nephew about it shortly after the second operation had been performed Francis‡ remarked that he would have been cautious in giving credence to the report he received had it reached him through the pages of a medical journal, coming to him from his former medical instructor, he could entertain no doubt of its truth He attempted at once, without success, to excite Velpeau and others of his surgical teachers to try it He next determined to etherize himself, before an appropriate audience, while he had a tooth pulled, this effort failed because he reached only the stage of excitement, and his obstreperousness was unpleasant Finally, in January, when Parisian doctors were beginning to receive English reports and to use ether with no great confidence, a Boston inhaler came to his hands complete with sponge and valves He demonstrated this to Roux and Velpeau, was invited by each of them to use the instrument in their clinics — which he

did with perfect success — and henceforward as he said with understandable complacency, the method took full possession of the French medical mind so that the inhalation of ether came to be employed in all surgical operations Friendship of a teacher for his student and the chance arrival of a Boston ether

FIGURE 5 Title Page of the Third Issue of Morton's "Letheon" This probably appeared in December 1846 It is a bibliophilic rarity, since only three copies have been found one in the Arm Medical Library, one in the Treadwell Library, of the Massachusetts General Hospital and one among the Warren papers in the Harvard Medical School Library

inhaler in France at the moment it was needed seemed the most active catalysts there

Curiously, the introduction of ether into the medical practice of the United States proved more difficult There were at least three understandable reasons for this conservatism, distance between medical centers so that news traveled slowly and, above all, skepticism Morton and Tenney were eager to publicize their work and possibly their way of doing it failed to attain general approval They

†What little is known of Dr Francis Willis Fisher is found in the archives of the Harvard Medical School the records of the Boylston Medical Society and Harnington's History of the Harvard Medical School

‡A committee of the American Medical Association consisting of G. W. Norris and Isaac Parrish Philadelphia, John Watson New York City A. L. Pearson, Salem, and Hugh H. McGuire Winchester Virginia wrote an excellent account of the development of anesthesia. Dr Pearson was a pioneer in the use of ether, lost his life five years later returning from the New York meeting Shortly after passing Norwalk the railroad car in which he was sitting plunged through an open drawbridge into the water below

profession of this vicinity, and that they are disposed to regard it as an effectual method of inducing complete insensibility under the most cruel operations, by means easily applied, entirely controllable, and productive of no subsequent bad consequences. It seems not easy to overrate the importance of such a discovery.

A Cunard mail steamer was due to sail for England about the first of December. Among a cargo of

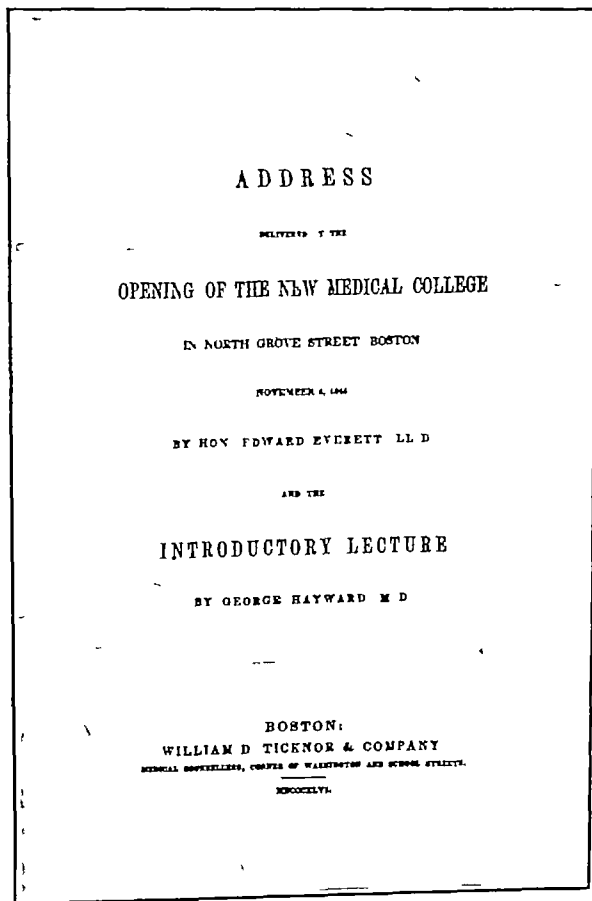

FIGURE 4 Title Page of Mr. Everett's Address

According to the Boston Medical and Surgical Journal, the address was clothed in beautiful language and was much admired for its elevated sentiments and elegance of expression. Mr. Everett believed that it was the first nonprofessional publication in which the use of ether was mentioned. The address was printed at the request of the students at the Harvard Medical School, and is misdated, presumably owing to their inexperience in proofreading.

other valuables, she carried copies of Mr. Everett's address and of Dr. Bigelow's paper, as well as letters describing the use of ether from Mr. Everett, Dr. Jacob Bigelow and Dr. Warren to sundry people of influence in Great Britain and France.

Dr. Francis Boott,* an Englishman who graduated from Harvard College in 1810, was a contemporary

*A sympathetic biography of Dr. Boott is found in the Harvard Archives Widener Library reprinted from *The Gardener's Chronicle* 1864.

and friend of Dr. Jacob Bigelow and Mr. Everett. After finishing college he returned to England, obtaining his medical education in Edinburgh. He practiced for a few years in London but soon inherited money enough so that he could do as he pleased. He retired from practice and took up botany as a hobby, but kept his hand on medical politics in general, particularly as they concerned University College, where he had taught and where he continued to serve on the Council. He had a talent for friendship, he had traveled across the Atlantic often enough so that he was in constant touch with Cambridge and Boston contemporaries.

The American mail arrived about the middle of December, and Dr. Boott† opened a letter from his friend Jacob Bigelow with usual relish and studied its contents with particular care. The letter read as follows:

November 28, 1846

Boston

My dear Boott:

I send you an account of a new anodyne process lately introduced here, which promises to be one of the important discoveries of the present age. It has rendered many patients insensible to pain during surgical operations and other causes of suffering. Limbs and breasts have been amputated, arteries tied, tumors extirpated, and many hundreds of teeth extracted without any consciousness of the least pain on the part of the patient.

The inventor is Dr. Morton, a dentist of this city, and the process consists of the inhalation of the vapour of ether to the point of intoxication. I send you the *Boston Daily Advertiser*,‡ which contains an article written by my son Henry, and which is extracted from a medical journal, relating to the discovery.

Let me give you an example. I took my daughter Mary, last week, to Dr. Morton's rooms to have a tooth extracted. She inhaled the ether about one minute, and fell asleep instantly in the chair. A molar tooth was then extracted, without the slightest movement of muscle or fibre. In another minute she awoke, smiled, said the tooth was not out, had felt no pain, nor had the slightest knowledge of the extraction. It was an entire illusion.

The newspaper will give you the details up to the date, since which other operations have been performed with uniform success.

Since college days Dr. Boott had known that anything Dr. Bigelow said was always true. On the morning after he had received the letter he got hold of some ether, Miss Lansdale, who had a molar tooth of which she wished to be rid, and Dr. Robinson, a dental surgeon, in the presence of Mrs. Boott and his two daughters, he etherized the lady and watched Dr. Robinson extract her tooth, painlessly and without difficulty. He then reported the matter to his friend Robert Liston, who, in turn, realizing that anything Dr. Boott said was true, immediately used ether at the University College Hospital in a case of thigh amputation and in a case requiring removal of the great-toenail, in both cases with excellent results.

I believe that this account outlines the pathway through which the discovery of ether reached Eng-

†From a description of this event it is clear that Dr. Boott was one of those who received a copy of Mr. Everett's address.

‡The *Boston Daily Advertiser* for November 19 reprinted Dr. Bigelow's article in full. This is the first complete and contemporaneous reprint with which I am familiar. The *Lancet* for January 2 1847 reprinted the *Boston Daily Advertiser's* reprint.

THE HOSPITAL — A LOOK AHEAD*

Some Aspects of Clinical Investigation

GEORGE R. MINOT, M.D.†

BOSTON

CLINICAL investigation has been conducted in the Massachusetts General Hospital with ever-increasing frequency and significance. In the future the hospital will continue to be a leader in such work, which will be developed more than ever before. From research of today come new forms of treatment tomorrow. It is treatment that patients are particularly concerned about. The physician, by investigative means, learns much about the etiology and diagnosis of disease, and investigative studies give information of a wide sort to the physician and the scientist.

This type of work is often done in conjunction with medical schools, but the work is frequently done entirely at the hospital by clinicians. Research of the clinical sort begins at the bedside. The needs of the patient urge the physician to make his scientific inquiries. Indeed, it may be said that research begins in the library, for the literature must be explored to determine what has already been accomplished. A good working library like the Treadwell Library is of great value to the hospital, but the members of the hospital must also make use of such libraries as the Harvard Medical School Library and the Boston Medical Library, where many books and scientific journals are at hand.

A clinical investigator cannot be defined by a rule of thumb. He must be an able clinician and one with wide interests who understands human beings and can act wisely for all the multiple aspects of a given patient. He must have an ardent desire to seek knowledge by scientific methods, as well as a wish to advance knowledge so that succeeding investigators will find the results nearer the ultimate goal.

Descriptions of previously unrecognized conditions often depend on the observation of several cases and not on planned investigation. The collection of proper information over long periods to formulate knowledge about prognosis, which in many chronic conditions is imperfect, represents a simple type of investigation. There is need for more accurate work of this sort. The question of the origin or cause of disease is of particular importance

to the clinical investigator and may require intricate and complicated studies.

The clinical investigator can study the problem by various methods at his command and with the aid of laboratories of various sorts. The search for truth regarding the laws of Nature is fundamental. One of the things that may be of great advantage in future investigation is co-operation among physicians, scientists and all types of scholars trained in different ways and at different sorts of institutions. Such co-operation, when spontaneous, is fruitful, but when compulsory, may be sterile.

This hospital will become even more of an educational center to train young men to be all types of physicians and surgeons. Among these men are future general practitioners. Such persons will always be of great value to the community and deserve to be looked up to.

The hospital will, of course, always continue to take care of patients and will investigate disease with increasing frequency, and although today it may be regarded as a consulting center, in the future it will certainly be considered a vital consulting center. The hospital is not competing with doctors, it is indeed helping them.

One must expect more full-time men at work at this hospital. I emphatically do not mean men who are not permitted to see private patients.

The importance of public education has been growing, and the hospital may be expected to take a leading part in such work. A preventive-medicine clinic is something we may expect. Preventive work has a broad conception — it must include all activities to increase health. Doctors must plan to construct as well as to reconstruct health. When the patient reports to the Out Patient Department in the future, he may even ask to go to the preventive-medicine clinic, and the public must be trained to appreciate the significance of preventive medicine, so that people will voluntarily go to such a clinic.

A growing understanding of the numerous factors that cause disease will determine in part the future course of preventive medicine. There is the prevention of disease and of health depreciation by the attainment of better general health. The chief objectives of preventive medicine have been to reduce things harmful in the environment and to increase the body's immunity.

The control of infectious diseases is increasing, and yet devastating epidemics occur. Chronic progressive diseases characteristically frequent in the

 †Presented at a symposium "The Hospital in the Community" held during the Esther Dyer Centenary of the Massachusetts General Hospital, Boston, October 16, 1946.
 Professor of medicine, Harvard Medical School; director, Thorndike Memorial Laboratory, Boston City Hospital; visiting physician, Boston City Hospital; member, Board of Consultation, Massachusetts General Hospital.

kept track of the literature on the use of ether as it accumulated and issued informative circulars from time to time in the form of a small pamphlet entitled "Letheon." The various issues of this unusual publication were more or less like present-day commercial advertisements and had little effect. The *Boston Medical and Surgical Journal* printed more serious articles, but these reached few physicians south of Massachusetts. By degrees, however, the fame of ether after its trip abroad came back to the United States through British and French medical journals. With human perversity physicians on this side of the Atlantic seemed willing to accept a procedure advocated in Boston only when it had the stamp of foreign approval. The New York Hospital began to use ether in the early spring of 1847, and a little later, surgeons at the University of Pennsylvania and the Jefferson Medical College took it up. By 1848, when the American Medical Association met, ether had come into its own over the entire world.

* * *

To my mind, this curious cycle of episodes is worth remembering. Chance played a large part in making the Ether Dome as famous as it is. If Mr. Tenney had happened to be a less aggressive reporter, if the Thursday-Evening Club had not held its first meeting when it did, if Professor Peirce had been able to fill his engagement to speak at the meeting of the Academy, if Mr. Everett's daughter had developed her toothache a few days earlier, if Dr. Boott had gone to college in Cambridge, England, instead of in Cambridge, Massachusetts, or if Francis Fisher had been assigned to another preceptor than his uncle, the whole story of ether might have been dif-

ferent. And without friendship — Mr. Tenney's friendship for Dr. Morton, Dr. Warren's friendship for the Bigelows, Dr. Jacob Bigelow's friendship for Dr. Boott, Dr. Boott's friendship for Robert Liston, and Dr. Fisher's friendship for the Hospital and his nephew — Mr. Eben Frost's toothache might have been of no great interest to anyone but himself, and the first use in Boston of ether as an anesthetic agent might have been insignificant.

Even in these days when science has complicated practice and research is so complex, it may be well to keep in mind the importance of two such simple imponderables as chance and friendship. Chance will always play an unpredictable part in shaping new ideas, medical investigators must not be led astray by the lure of intricate machinery but must ever be alert to use their eyes to see unexpected, apparently insignificant occurrences that may later prove to be great events. Friendship will always be necessary to our art so that as many people as possible may work together to develop its future for the greatest common good.

proteins and fruit. These foods are not luxuries but necessities.

Elvehjem³ has noted that diets containing 9 per cent of casein produce good growth but that when 6 per cent gelatin is added, poor growth results. Tryptophan or protein low in tryptophan or nicotinic acid counteracts this retardation. Thus, poor-quality proteins may in the future be regarded as more harmful than a diet low in protein.

The methods used in the diagnosis of subclinical deficiencies in human beings obviously need new and improved chemical measurements. Mild deficiencies are not obvious, and may be difficult to detect. Tests of various kinds will be improved and developed to aid in the understanding of such conditions. Hyperthyroidism, tuberculosis, pregnancy and the like may increase the need for certain dietary factors and may lead to suboptimal nutrition. Nutritional deficiency in man is of a multiple nature.

The relation of nutrition to dental caries needs much study. Dental caries is the most widespread nutritional defect, one or more nutritional factors involved may be harmful, or the lack of a factor or factors may be causative. Diets high in fermentable sugar may induce dental caries, and increased intakes of fat and protein minimize dental caries. The relation of nutrition to resistance to diseases and to infectious processes also needs further study.

The essential trace elements, such as cobalt and zinc, that occur in living matter but whose importance is unknown stand as a challenge to physiologists and nutritionists. It is recognized, however, that men working in cobalt (radioactive) and pitch-blend mines frequently develop bronchiogenic carcinoma.

One must recognize such work as that of Rhoads,⁴ in which indol causes no anemia in dogs with proper diets but induces severe anemia when the animals are given black-tongue diets. Butter yellow is tolerated by normal animals, but if the vitamin B complex level is low, cancer develops. Rhoads has also shown that dietary constituents such as riboflavin and casein protect animals against the carcinogenic effects of butter yellow (*p*-dimethylaminoazobenzene).

Cancer research is a great responsibility that confronts scientific medicine. Cancer is a disease predominant in the later decades of life. There has been great improvement in the methods of diagnosis and treatment of internal cancer, and yet the death rate per million population has been increasing. People must learn to seek competent medical advice when an early suspicious sign or any abnormality that might predispose to the disease is noticed. Prompt and effective treatment for cancer is essential.

There is often no indication of why a cancer develops. Occasionally, the occurrence of chronic irritation of potential tumor sites is well recognized,

as in the mouths of tobacco chewers. Cancer may involve almost any part of the body, but the digestive tract is usually affected.

One of the causes for the neoplastic state seems to be viruses.⁵ Some of the viruses are products of disordered cell metabolism, and others are living entities. Tumors induced in mice by methyl cholanthrene are not influenced as those resulting from butter yellow are by the addition of one or more substances of a similar sort in the diet. In such cases it does not seem that living viruses play a role. The high incidence of liver cancer and cirrhosis in the African Bantus and the poor diet consumed by these people suggest a causal relation. Whatever the cause of cancer may be, a great many studies are needed to determine clearly the fundamental aspects.

Disorders of the blood must not be forgotten in clinical investigative studies. Leukemia is considered by some to be comparable to cancer. No one has ever recovered from this disease, but x-ray and allied therapy is palliative. Chemotherapy may offer some hope. Investigators would like to identify a specific component of the cancer cell and of the leukemic cell. Indeed, what is the difference between a leukemic and a normal cell? For some mysterious reason the blood cells in leukemia grow in a purposeless manner. A radioactive atom might be incorporated in a leukemic cell, in the hope that in some manner leukemia would be vanquished.

Certain anemias also need elucidation. The first evidence that there are two distinctive components of liver extract effective in nutritional macrocytic anemias came from the observations of Wills⁶ on monkeys. In these animals, in which anemia had been produced by the feeding of a defective diet similar to that of patients with tropical macrocytic anemia of pregnancy in India, a highly purified liver extract effective in pernicious anemia was found to be ineffective. This finding led to a similar demonstration of the inefficacy of purified liver extract in human patients. The cases in this group include certain patients with macrocytic anemias of the tropics and of pregnancy, as well as so-called "refractory anemias" with megaloblastic bone marrow. Watson and Castle⁷ have studied this problem. Whether such patients require the active principle of liver extract that is effective in pernicious anemia, as well as an additional factor present in less refined liver extract or only the latter material, is unknown. As yet, it has not been determined whether folic acid, present in only trivial amounts in liver extract, is as effective in these cases as it is in pernicious anemia.

Rheumatoid arthritis is being studied expertly here by Dr. Bauer and his associates. The nature and course of this disease necessitate a detailed clinical and laboratory study over a long period. Rheumatoid arthritis is a disease of young adults and often continues throughout life. It is more

later years of life will continue to assume greater and greater significance. Infections of childhood will become rarer perhaps because of better control and better treatment. It may even be supposed that cancer could be controlled by the injection of some mysterious chemical comparable to insulin in diabetes mellitus or penicillin in pneumococcal pneumonia.

The degenerative diseases such as those with high blood pressure will constitute an ever-increasing threat to national health. To be sure, these diseases have occurred for many thousand years, but their social importance is new. There is now a rapidly increasing number of elderly people, who are presenting new problems. The hospital will concentrate more and more on problems of health in later years of life, but will continue to attack diseases frequent in youth.

Effective prevention is usually possible only when the whole history of causation is known. The etiology must often be considered to include multiple causative influences.

Personal preventive medicine supplements public-health efforts. The early discovery of a disorder that will be more frequent in the future will allow the maximum benefit from therapy. Comprehensive periodic health consultations are essential—not a purely routine physical examination but a study that comprises a detailed history and complete consideration of the patient as a person, including the analysis of such habits of living as diet, rest and work. Thoroughness and individualization will always be needed.

Education in health for all age groups and by every means available will be an increasingly important medical problem. Sensationalism must be avoided. "The future of preventive medicine is bright whatever its precise course may be," Sleghtitz¹ said, adding "Medical science can give health to no one, but it is daily becoming more competent in guiding those who wish to *earn* health." Good health can be bettered, and man made to live longer, these are among the effects of the prevention of actual disease.

There are types of clinical investigation that demand organized study by institutions so that data can become available over many years and generations before final analysis is made—for example, creative work to determine the exact qualitative and quantitative influence, on thought and social life, of dietary factors alone or in combination and under varying climatic environments. The history of the people of the world could perhaps be written in terms of diet, as Zinsser² has done in terms of epidemics. Initiative, progress, success and the happiness of a people tend to go hand in hand with an abundance of food and a good diet.

Adequate and good food is fundamental to health. The most fertile field in the world of medical research today is nutrition. Nutritional, especially

vitamin, deficiency leads to ill health and distinctive diseases. Niacin, for instance, prevents pellagra, but mild deficiency of various vitamins may lead to chronic malnutrition, although the patient may take a sufficient number of calories not to lose weight. Nutritional studies regarding the lack of food elements, the faulty distribution of food and the great value of proper food for children must in future be a primary concern.

It is quite possible that more vitamins will be identified. Little is known regarding the taste appeal of foods, and information of this sort lies ahead. I wonder why some people really like liver and others dislike it. Others object to kidneys or oysters, whereas some think they are delicious.

The composition of foods should be known. Such studies may relate to enzymes and their mechanisms, which are not familiar subjects at present. Much lactose in the diet may increase the synthesis of riboflavin, but it may decrease that of other factors. Fat may reduce the production of riboflavin in the gastrointestinal tract. Natural diets may give effects distinctly different from those of synthetic diets, but it is the natural diet that man uses. The world is full of food potentialities, and the anticipated demands for foods of superior nutritive quality need re-evaluation.

An adequate dietary history is difficult to obtain, and yet it reveals a great deal about the nutrition of the patient. In the future, customs may change as they have in the past hundred years—fresh fruit is vastly more frequent, today, and red meat is rarer. Greater attention should be paid to dietary histories and to the importance of the effects of foods. One cannot feed by pure chemistry—the diet may be varied and yet deficient. A patient may be ashamed to admit that his diet is poor. This may be due to eccentricity, lack of teeth or ignorance, and the role that such difficulties play must be appreciated.

One must distinguish between what the community has to eat and what the individual has. The patient may be a fussy, finicky eater and may say about certain foods if the question is brought up, "The family have them but I do not eat them." Indeed, social adjustments may be vital before the correct food has been obtained or digested. It should be remembered that to order a diet is one thing but to cure a patient is another. A proper diet of natural foodstuffs is all that is necessary for prevention of disease caused by faulty nutrition.

It must also be realized that little is known about optimal nutrition as opposed to usual nutrition. The former should be the goal—not merely adequate nutrition.

Rising income is associated with increased consumption of milk, fruit, eggs, vegetables and meat and with better growth in children and improved general health. Such foods are the protective foods—the ones rich in vitamins, minerals and first-class

proteins and fruit. These foods are not luxuries but necessities.

Elvehjem² has noted that diets containing 9 per cent of casein produce good growth but that when 6 per cent gelatin is added, poor growth results. Tryptophan or protein low in tryptophan or nicotinic acid counteracts this retardation. Thus poor-quality proteins may in the future be regarded as more harmful than a diet low in protein.

The methods used in the diagnosis of subclinical deficiencies in human beings obviously need new and improved chemical measurements. Mild deficiencies are not obvious, and may be difficult to detect. Tests of various kinds will be improved and developed to aid in the understanding of such conditions. Hyperthyroidism, tuberculosis, pregnancy and the like may increase the need for certain dietary factors and may lead to suboptimal nutrition. Nutritional deficiency in man is of a multiple nature.

The relation of nutrition to dental caries needs much study. Dental caries is the most widespread nutritional defect, one or more nutritional factors involved may be harmful, or the lack of a factor or factors may be causative. Diets high in fermentable sugar may induce dental caries, and increased intakes of fat and protein minimize dental caries. The relation of nutrition to resistance to diseases and to infectious processes also needs further study.

The essential trace elements such as cobalt and zinc, that occur in living matter but whose importance is unknown stand as a challenge to physiologists and nutritionists. It is recognized, however, that men working in cobalt (radioactive) and pitch-blend mines frequently develop bronchiogenic carcinoma.

One must recognize such work as that of Rhoads,⁴ in which indol causes no anemia in dogs with proper diets but induces severe anemia when the animals are given black-tongue diets. Butter yellow is tolerated by normal animals, but if the vitamin B complex level is low, cancer develops. Rhoads has also shown that dietary constituents such as riboflavin and casein protect animals against the carcinogenic effects of butter yellow (*p*-dimethylaminoazobenzene).

Cancer research is a great responsibility that confronts scientific medicine. Cancer is a disease predominant in the later decades of life. There has been great improvement in the methods of diagnosis and treatment of internal cancer, and yet the death rate per million population has been increasing. People must learn to seek competent medical advice when an early suspicious sign or any abnormality that might predispose to the disease is noticed. Prompt and effective treatment for cancer is essential.

There is often no indication of why a cancer develops. Occasionally, the occurrence of chronic irritation of potential tumor sites is well recognized,

as in the mouths of tobacco chewers. Cancer may involve almost any part of the body, but the digestive tract is usually affected.

One of the causes for the neoplastic state seems to be viruses.⁵ Some of the viruses are products of disordered cell metabolism, and others are living entities. Tumors induced in mice by methyl cholanthrene are not influenced as those resulting from butter yellow are by the addition of one or more substances of a similar sort in the diet. In such cases it does not seem that living viruses play a role. The high incidence of liver cancer and cirrhosis in the African Bantus and the poor diet consumed by these people suggest a causal relation. Whatever the cause of cancer may be, a great many studies are needed to determine clearly the fundamental aspects.

Disorders of the blood must not be forgotten in clinical investigative studies. Leukemia is considered by some to be comparable to cancer. No one has ever recovered from this disease, but x-ray and allied therapy is palliative. Chemotherapy may offer some hope. Investigators would like to identify a specific component of the cancer cell and of the leukemic cell. Indeed, what is the difference between a leukemic and a normal cell? For some mysterious reason the blood cells in leukemia grow in a purposeless manner. A radioactive atom might be incorporated in a leukemic cell, in the hope that in some manner leukemia would be vanquished.

Certain anemias also need elucidation. The first evidence that there are two distinctive components of liver extract effective in nutritional macrocytic anemias came from the observations of Wills⁶ on monkeys. In these animals in which anemia had been produced by the feeding of a defective diet similar to that of patients with tropical macrocytic anemia of pregnancy in India, a highly purified liver extract effective in pernicious anemia was found to be ineffective. This finding led to a similar demonstration of the inefficacy of purified liver extract in human patients. The cases in this group include certain patients with macrocytic anemias of the tropics and of pregnancy, as well as so-called "refractory anemias" with megaloblastic bone marrow. Watson and Castle⁷ have studied this problem. Whether such patients require the active principle of liver extract that is effective in pernicious anemia, as well as an additional factor present in less refined liver extract or only the latter material, is unknown. As yet, it has not been determined whether folic acid, present in only trivial amounts in liver extract, is as effective in these cases as it is in pernicious anemia.

Rheumatoid arthritis is being studied expertly here by Dr. Bauer and his associates. The nature and course of this disease necessitate a detailed clinical and laboratory study over a long period. Rheumatoid arthritis is a disease of young adults and often continues throughout life. It is more

frequent in women than in men and more prevalent among the poor. It may begin insidiously or abruptly. Symptoms may disappear for several years, but recurrence is the rule. States of anxiety may precipitate an attack. The patients are apt to suffer from mental depression. This disease is of national importance because, although seldom fatal, it cripples many.

The factors regulating effusions in rheumatoid arthritis and those regulating the rate of formation and composition of synovial fluid are little known. Studies on mucin, which is obviously involved in rheumatoid arthritis, are needed. Ascorbic acid may play a role in the destruction of mucin. Greater knowledge should be acquired regarding the pathogenesis of the subcutaneous nodules characteristic of the disease. Studies of this sort as well as the psychiatric aspects of patients with arthritis—indeed, matters pertaining to all aspects of the disease—demand investigation.

Physics will concern investigators much more than in the past. Physicists and other natural scientists may even aid in the study of medicosocial problems. The electron microscope gives information about viruses and the diseases they cause. It can scarcely be foretold what will be discovered concerning the origin of living matter.

* * *

Many diseases and problems besides those mentioned will be studied at this hospital, and undoubtedly great progress will be made under the able leadership of Dr. J. H. Means and his successors. One can never tell when the cure for some dread disease is right around the corner.

The public must be educated to look on research as an essential activity and to understand the practical application and the enormous cost of undertaking investigation. No member of a community passes through life without receiving directly or indirectly the benefits of research done in such a great hospital as this. We all owe much to the Massachusetts General Hospital.

ATELECTASIS AS A FACTOR IN THE MEDICAL TREATMENT OF PLEURAL EMPYEMA THE NECESSITY OF COMBATING ATELECTASIS BY REMEDIAL BREATHING EXERCISES

FELIX G. FLEISCHNER, M.D.*

BOSTON

THE therapeutic management of empyema of the pleura has been revised because of the recent favorable experiences with penicillin. The treatment by open drainage after rib resection has been the generally accepted procedure in adults in practically all cases except those due to tuberculosis, actinomycosis and malignant neoplasm; this approach was based on the experiences in World War I and the report of the American Empyema Commission (1918), which clarified the rules for correct timing. Since then chronic empyemas have been seen less often than formerly.

Chronic empyemas are usually grouped in two categories: cases in which the original condition has never been recognized and a collection of pus has remained after the disease had been overcome by the body, and those in which the condition is a sequel of an acute empyema treated in the conventional way with the effect of overcoming the disease but without effecting the complete evacuation or

resorption of the pus. The unsatisfactory results in this group are usually due to too early removal of the drainage tube, to an improperly placed opening so that a pool of pus remains at the bottom of the pleural cavity, to encapsulated pockets or to a foreign body—usually a tube—in the empyema cavity. In both groups, those with and without surgical treatment, the persistent empyema may be maintained by incomplete expansion of the lung, owing to a bronchopleural fistula, thickening of the pulmonary pleura and atelectatic fibrosis of the lung. In pleural exudates and empyemas, fibrin is deposited on the pleura in varying amounts. The usual roentgenologic terminology is inaccurate in that the deposits are often described as thickened pleura. In the early stages these masses of soft-tissue density represent nonorganized fibrin deposits that undergo later organization through the ingrowth of capillaries from the underlying pleura. Thus, the roentgenologic term is meant to comprise both conditions, since there is no way of distinguishing the nonorganized layer of fibrin deposit, still

*Instructor in radiology, Harvard Medical School and Tufts College Medical School; director, X-Ray Department, Beth Israel Hospital.

capable of being resorbed, from the final organized product, which represents pathologically thickened pleura

It has been shown, clinically and experimentally, that the parietal and the pulmonary pleuras behave in a different manner in pleural inflammations, whether they are pneumococcal or tuberculous, serofibrinous or purulent.^{1,2} In the majority of cases, whereas thick layers of the deposits are found

pleural effusion begins to be resorbed, the obstructive atelectatic areas resist more obstinately the expanding traction because the factors causing the obstruction, such as kinks of the bronchi and accumulated secretion, are apt to persist. The presence of obstructive atelectasis, even if local and patchy, counteracts the tendency toward re-expansion. As a consequence of the collapse, the moist surfaces of capillary bronchioles come in contact with each

FIGURE 1 Pleural Effusion before (A) and after (B) Thoracocentesis
Note the plate-shaped area of obstructive atelectasis (arrow) in the latter roentgenogram

along the chest wall, only thin deposits or none at all are observed on the visceral pleura. This does not hold true for the posthemothoracic empyemas that develop after blood coagulums have been laid down more or less uniformly. A somewhat different behavior of the pleural surfaces, however, is recognizable even in such cases. As pointed out by Samson et al:³ "For some reason as yet unexplained, the peel over the parietal pleura is always thicker than that on the visceral pleura." The thinness of the deposits on the pulmonary pleura suggests that thickening of the pleura probably plays a minor role in the maintenance of the collapsed state of the lung in the usual nonhemothoracic empyema. It appears that, in the majority of cases, atelectasis is more important in hampering the re-expansion of the lung.

According to the textbooks, the atelectasis occurring with pleural effusion is of the compression type. The extrinsic pressure squeezes all the air from the alveolar sacs until they collapse and the capillary bronchioles also collapse. The matter, however, is not so simple as that. There is ample evidence from pathological and roentgenologic observations that, in addition to compression atelectasis, obstructive atelectatic processes in varying degrees occur. Although the compressed lung should respond readily to the expanding pull as soon as the

other, and great force is needed to overcome the surface tension to separate them again.

Pathological evidence of obstructive atelectasis with pleural effusions has seldom been described, although it is easily observed. At autopsy in cases with moderate pleural effusion, the atelectatic portions of the lung are identified by the depression of the surface, dark color and firmness. Quite often, the borderline toward the aerated area coincides with the pattern of the interlobular septums on the lung surface, moreover, isolated or multiple lobules, which are elevated, pale and air filled in the midst of otherwise atelectatic areas, are observed and on the other hand, beyond the compact atelectatic zone, isolated atelectatic lobules, depressed, dark red and firm in the midst of a well aerated section, frequently occur. When atelectatic areas are cut through, the surface exposed is not dry and gray as would be expected in compression atelectasis but dark red and moist, with much fluid oozing out, thereby showing the picture of obstructive or resorption atelectasis. In other cases the edge or even larger portions of the middle and lower lobes have been turned up, owing to the buoyancy of the lung floating in the fluid. Sometimes such a turned-up edge is found to be fixed by recently formed adhesions, which prevent the restoration of the normal position, the linked bronchi do not straighten

out, and the parenchyma served by them remains in its atelectatic condition. These observations on the gross morphologic appearance of the lung in pleural effusion show that, in addition to compression, obstructive atelectasis—due to collapse and kinking of bronchi and to retention of secretion in

lung. If the lung persists in its atelectatic condition for a longer time, however, it is apt to suffer irreparable alterations. Pleurisy is not restricted to the superficial layers of the pulmonary pleura. In chronic empyema the inflammation extends into the superficial interlobular septums and deeper,

FIGURE 2 Diagram Illustrating Three Possible Events in the Course of Pleural Effusion without and with Persistent Atelectasis

Res = resorbing pull, Atel = atelectatic resistance of the lung against its re-expansion, Med = rigidity of the mediastinum resisting lateral shift

In A, the resorbing pull is large, and the mediastinum is stable. The atelectatic lung is easily re-aerated, and complete recovery results.

In B, the atelectasis is rigidly maintained, the resorbing pull is strong and the mediastinum is movable. Resorption of the exudate, persistent atelectasis and deformity of the chest result.

In C, the atelectasis is rigidly maintained, and the mediastinum is immobile, a residual empyema pocket and atelectatic induration of the lung result.

the poorly ventilated dependent portions of the lung—occurs.

Roentgenologic observations also confirm the presence of obstructive atelectasis in pleural effusion. More extensive collapse of one lobe or lobar segment, as well as unusual arrangement of the pleural fluid in the absence of pleural synechia, is analogous in appearance and origin to the selective collapse in pneumothorax and is due to obstructive atelectasis. If the mediastinum is pulled to the side of the effusion during the period of resorption or following a thoracentesis, the presence of obstructive atelectasis is indicated. Furthermore, I have observed plate-shaped areas of obstructive atelectasis immediately after thoracentesis (Fig. 1).

The functional aspect of these facts has recently been confirmed. In an analysis of the effects of pleural effusion on respiration, Altschule and Zamcheck⁴ showed that the functional reserve (supplemental) air, as well as the complementary air, increases only moderately eighteen hours after thoracentesis. Restoration of the vital capacity to its normal value takes about a month, indicating that great resistance must be overcome to reventilate the atelectatic lung.

This is the situation so long as no irreparable pathologic changes have occurred in the collapsed

larger interstices. Lindblom⁵ summarized his careful studies by pointing out that the longer the duration and the greater the purulence of a pleural effusion, the more extensive the pleurogenic interstitial pneumonia and the resulting fibrosis.

Atelectasis persisting for a long period, even without supervening inflammation, may in itself incite fibrosis of the lung. It has been shown that the occasional edema of the interstices may persist for a long time, resulting in fibrosis. In this way the interlobar septums and the perivascular and peribronchial interstices are widened. The involved area of the lung loses its plasticity and becomes more rigid.⁶ Residual or supervening infection in the lung or bronchi may add to the permanent loss of elasticity of the involved portion of the pulmonary tissue.

All these developments initiated by long persistent atelectasis have a crippling effect on the lung; moreover, they prevent the re-expansion, adequate diminution of the residual empyema cavity and final resorption of the empyema.

The aim of the treatment of pleural empyema is twofold: to combat the inflammatory disease with all its complications and to rehabilitate the lung. The classic surgical procedure combined with supportive medical treatment is directed at both aims.

Purely medical treatment with bacteriostatic or antibiotic drugs may stop the activity of the disease, and the body may or may not successfully handle the residual empyema. The problem of residual empyema similarly exists if the pleural taps are not continued with enough frequency, or if it is impossible to withdraw the fluid further, because it becomes inspissated or encapsulated in pockets

means, mobilized by the body to resorb the residual empyema, must overcome the tendency of the lung to maintain its collapsed condition. Since this resorption occurs in a relatively rigid cavity, the thoracic cage, a considerable pull must be exerted on the lung, for the present purpose, this may be called the "resorbing pull." The increased intrinsic resistance of the lung to re-expansion was briefly

FIGURE 3 Case 1

The roentgenogram on the left shows postpleuritic contraction of the right lung (Tr = trachea, C = carina, L = border of the left lung herniated into the right half of the chest). The x-ray film on the right is a bronchogram of the right half of the chest, revealing obliteration of most of the smaller bronchi and bronchiectasis of the few patent ones (Tr = trachea, Es = esophagus).

that cannot be reached with the needle. I have recently seen a series of chest roentgenograms in such cases in which residual pockets of retained empyema, thickening of the pleura and deformation of the chest resulted from penicillin treatment without or with insufficient evacuation of the empyema.

A knowledge of the mechanical forces involved is essential to a better understanding of the occurrence of residual empyemas and to the planning of support for the body in its endeavor to resorb the fluid.

There have always been cases of pleural empyema in which the disease subsided and healed in spite of conservative treatment, incomplete surgery or no therapy. Some healed with few sequelae, others with permanent damage to the underlying lung, others with residual chronic empyemas, and still others with gross chest deformities; there were often combinations of all these sequelae.

There are basically three forces that in combination, control the rate of resorption of pleural effusions. The structural, physical and biochemical

mentioned above. For simplicity, the factors opposed to the expansion of the lung may be considered under the label "atelectasis." The half-chest cage in which the resorption is to occur is made up of the rib cage, the diaphragm and the mediastinum. The mediastinum and diaphragm can be pulled into the half chest to a considerable degree. Also, approximation and bending of the ribs may contribute to the diminution of space. Again, for simplicity, this rigidity of the chest wall opposing its being pulled into the chest cavity may be regarded as the rigidity of the "mediastinum" against lateral shift.

The action of the three forces is presented diagrammatically in Figure 2. In the resorption of a large pleural effusion three different developments are possible. In the first place the resorbing pull is large, the atelectatic resistance of the lung against expansion is weak and the mediastinum and the other constituents of the half chest wall are stable and firm. This represents the ideal development. The exudate is resorbed and the lung is completely

expanded without displacement of the mediastinum and deformity of the chest. Secondly, the atelectatic condition of the lung — or fibrous or pleural rigidity — cannot be overcome. The resorbing pull, although strong, cannot expand the lung but is powerful enough to attract the mediastinum, as well as the diaphragm and ribs. This occurs in cases in which

became fibrosed, the lobar bronchi were patent and ended in few large bronchiectatic cavities (Fig 3). The mediastinum, however, yielding to the absorption pull, shifted over to the right, and the left lung, overlapping into the right half chest, occupied the space made free by the contracting right lung. Thus, the right pleural cavity gradually decreased in size and allowed the empyema to be resorbed.

CASE 2 This patient with tuberculosis of the upper lobe was treated with artificial pneumothorax. Pleural exudate

FIGURE 4 Case 2

This roentgenogram shows spontaneous hydropneumothorax after perforation into a bronchus of a chronic pleural empyema. The arrow indicates the fluid level.

the pleural effusion is finally resorbed, the mediastinum is displaced, the chest is grossly deformed and the lung remains in atelectatic fibrosis with or without secondary changes, such as bronchiectasis. The third possible development occurs when the resorbing pull is too weak to overcome the atelectatic rigidity of the lung and also too weak to move the mediastinum, the diaphragm and the ribs. The pleural cavity is not reduced in size, and the empyema is not resorbed. This situation is quite similar to that in any abscess in a rigid cavity.

The following cases represent, respectively, the second and third developments and a combination of all three.

CASE 1 Eighteen years before he came under observation this patient had had a pneumonia and pleural empyema, which had been treated conservatively, without open drainage. His condition did not change during the following 6 years. There was maximal retraction of the right half chest. The right lung, collapsed by the large empyema at the time of the acute disease, remained in its atelectatic condition and

developed, filling the pleural cavity, and the refilling of the pneumothorax was discontinued after 1½ years. The patient recovered completely and was re-examined repeatedly, the findings always remaining unchanged. Seven years later she suffered a serious fall, following which she started coughing up large amounts of purulent fluid. X-ray examination showed a collapsed, condensed lung and a hydropneumothorax in the rigid pleural cavity (Fig 4). This was a typical history of internal perforation of a chronic pleural exudate. The lung, collapsed during the early period of the pneumothorax treatment, underwent fibrosis and became inexpandible. Although the disease healed, the exudate could not be reduced in size owing to the rigidity of the collapsed lung and the fixation of the mediastinum.

CASE 3 This patient had a lobar pneumonia followed by empyema in 1927, incompletely treated by surgery. For many years after clinical recovery the chest condition did not change. Re-evaluation 16 years later revealed a pleural cavity of medium size, filled at the left base with thick sterile pus, and a left lower lobe that was collapsed and fibrosed, as clearly shown by the approximation and shortening of the moderately dilated bronchi (Fig 5). The complete resorption of the empyema had been mechanically prevented by the atelectatic fibrosis of the lower lobe.

The sequelae of incomplete or absent expansion of the lung have occasionally been effectively prevented or combated by the institution of breathing exercises (Hofbauer⁷). If the pain and the reflex inhibition are overcome, if the weakened respiratory muscles

With the present-day penicillin treatment both these difficulties are eliminated. The disease manifested by systemic signs and symptoms has a much shorter course and is usually overcome within one or two weeks. The temperature and pulse rate

FIGURE 5 Case 3

This film shows a residual pleural empyema, sixteen years after incomplete surgical treatment. The bronchogram reveals the collapsed atelectatic lower lobe and the lingula of the upper lobe.

of the involved half chest are put to active work and if the atelectatic lung is forcefully reventilated, it recovers its elasticity, expands and resumes its full function, facilitating mechanically the resorption of the residual pleural exudate. Such a regime has met with two adverse factors. The duration of the disease was long under incomplete surgical and conservative medical treatment, and there was ample time for the development of irreparable alterations in the lung and pleura, furthermore, the systemic signs and symptoms of active disease subsided slowly and almost imperceptibly, making it difficult to determine the time when active exercises could safely be begun.

return to normal levels, the appetite returns and the patient feels well. There may still be dyspnea, owing to the restricted breathing surface. There has not been much time for the establishment of irreparable damage to the lung and pleura. In addition, because of the rapid and more dramatic improvement, the time to start with active breathing exercises can be more easily chosen. Whether the patient will be restored to active physical work or fitted again for full respiratory capacity by breathing exercises may be determined according to the individual case. Such exercises are well known to the physiotherapists, they have been used successfully in European countries in the past and more recently

they have been given greater attention in the United States. Harken,⁸ in a recent review of the activities of the Thoracic Center of a United States Army hospital group in England, placed strong emphasis on the remedial breathing exercises for chest injuries

* * *

Under the influence of penicillin it appears that the future treatment of pleural empyema will be, for a large number of cases, nonsurgical. Whether or not the systemic administration of penicillin is reinforced by local injection of the drug into the empyema cavity, the most complete evacuation of the empyema by repeated pleural taps should be attempted. After the successful treatment of the disease, care of a residual sterile empyema should not be left to the body. Empyema should not be considered cured until there is complete re-expansion of the lung. Resorption is often delayed or impeded by atelectasis of the lung or — to a lesser degree — fibrous deposits on the pleura. Re-expansion and

restoration of the ventilatory capacity of the lung mechanically facilitate the resorption of exudate and prevent or reduce permanent invalidity of the lung and chest deformities. This reactivation of the lung can be promoted by proper breathing exercises

MEDICAL PROGRESS

ELECTROCARDIOGRAPHY*

LAURENCE B. ELLIS, M.D.†

BOSTON

IN 1940 a progress report was published to help orient physicians in general regarding the value and limitations of electrocardiography in the diagnosis and evaluation of heart disease.¹ The present article is not strictly a progress report. Rather, it is designed for those who have some basic knowledge of the subject but who have lacked time and opportunity to keep abreast of the recent developments in the field. No attempt has been made to review completely the voluminous number of articles that have been published in recent years, only a few major points are considered.

A recent development has been the perfecting of an electrocardiographic apparatus that inscribes the final record directly on paper instead of through the medium of photography. The practical advantages are obvious in providing a tracing that is immediately available at the bedside and obviates the trouble and expense of photographic developing. It remains to be seen whether technical difficulties and objections have been sufficiently overcome so that these machines will be reliable and sturdy enough for clinical use. All of them employ the audion-tube method of amplification, and most of them

inscribe the record by a heated stylus that melts a wax or plastic surface on the paper. At least one, however, utilizes an ink-writing device. There are at least four different models of these new machines currently on the market.

In the past few years emphasis in electrocardiographic studies has to some extent shifted. The period from the early 1920's until late in the 1930's was the halcyon time for descriptive, empirical electrocardiography. Many valuable data were amassed concerning electrocardiographic variations in different types of heart disease, and this technique in the assessment of various arrhythmias was particularly explored in voluminous detail. Moreover, during this period, the value of the electrocardiogram in the diagnosis of myocardial infarction was increasingly established.

In recent years more and more scrutiny has been given to the basic electrical principles involved and to correlations between clinical findings and experimental work. In a way this is a harking back to much of the fundamental work that was done in the field, especially by Sir Thomas Lewis. The painstaking work of Wilson and his collaborators*,^{2,3} through the years on the laws governing the electrical effects produced by the heart beat and especially on precordial and direct leads has now received the general recognition it merits. Today, no cardiac

†Associate in medicine, Harvard Medical School, assistant visiting physician, Boston City Hospital.

specialist would be considered really competent who was not conversant with some of the electrical principles underlying clinical electrocardiography. Bayler⁴ has presented a review of some of these basic electrical correlations, including vector analysis.

ELECTROCARDIOGRAPHIC VARIATIONS IN THE ABSENCE OF ORGANIC HEART DISEASE

It has been recognized for a long time that serious heart disease can exist with a normal electrocardiogram. In a recent study of 722 patients with heart disease, 223 had normal electrocardiograms.⁵ The converse situation has been less appreciated, but numerous recent articles testify to the relative frequency of abnormal tracings in persons with no detectable heart disease, as well as of the various extracardiac conditions that can alter the record. Thus, in observations on 500 unselected young adults, of whom only 14 had any clinical evidence of heart disease, Viscidi and Geiger⁶ found that 48.8 per cent had normal electrocardiograms. Most of the abnormalities were, it is true, minor. In a study of 1000 healthy aviators, Gravbiel et al.⁷ reported that the PR interval was less than 0.12 second in 13 cases and longer than 0.20 second in 16. The QRS interval exceeded 0.10 second in 35 cases, including 1 case of frank left bundle-branch block and 2 of the Wolff-Parkinson-White pattern. Other deviations from the normal were also reported. Stewart and Manning⁸ noted essentially similar results. In an analysis of electrocardiograms of 500 Canadian flyers 18 per cent were found to be borderline or abnormal and thus confirmed a previous study.⁹ Abnormal PR intervals were observed in 5 per cent, abnormal Q waves in 2 to 3 per cent, and diphasic or negative T₁ or T₂ waves in 0.5 to 1 per cent.

Elevation of the diaphragm and change of posture may alter the form and produce inversion of the T waves in the standard leads as well as the precordial leads.^{10, 11} This occurs especially in the upright position. It is seen particularly in persons with neurocirculatory asthenia.¹²⁻¹⁶ One explanation is that the inversion is due to a change in the position of the heart, but Wendkos^{15, 16} is of the opinion that it is the result of heightened sympathetic activity in the upright position. Some support for his thesis is found in the fact that the assumption of the upright position may shorten the PR interval.^{17, 18} Intra-abdominal disease can alter the form of the electrocardiogram,¹⁹ and even the eating of a meal may produce minor changes in the P and T waves,²⁰ which in borderline records might easily be interpreted as being due to acute heart disease. The difficulty of distinguishing between acute upper abdominal disease and acute cardiac accidents is well known, as is the frequency with which they may coexist.

What then are the bounds of normal in electrocardiography, since records that fall outside con-

ventional standards may be obtained from apparently normal persons? There is no final answer. These standards must still be accepted as being the best available. It is well to appreciate, however, that the electrocardiogram should be interpreted with caution, it is a useful adjunct in clinical diagnosis, but its findings should always be related to the clinical picture. As many mistakes are made from an overenthusiastic and undercritical reliance on electrocardiography as from a failure to utilize this technical aid.

It has been known for a long time that electrocardiographic changes occur in the course of rheumatic fever, and hence the electrocardiogram has been relied on a good deal in the differential diagnosis of this disturbance. Is it reasonable to assume therefore, that when electrocardiographic abnormalities occur in patients following acute respiratory infections, rheumatic fever is present? Rantz, Boisvert and Spink²¹ found that such changes occurred in 10.8 per cent of 185 patients with acute hemolytic streptococcus throat infections. These changes consisted of prolongation of the PR interval or of sharp inversion of the T waves, often in all three leads. These authors believed that rheumatic fever only follows hemolytic streptococcus infection and that the many manifestations that may occur, such as arthritis, fever and carditis, should be grouped together under the term "poststreptococcal state." It is the opinion of many authors that such electrocardiographic changes following infections are often nonspecific.^{22, 23} They have been found during and after pneumococcal pneumonia — a disease that is seldom associated with rheumatic fever.²⁴ Sometimes, following such infections of varied etiology, clinical myocarditis or pericarditis develops, and this may even be fatal.²⁵⁻²⁸ The administration of the sulfonamides has on occasion been accused of producing myocarditis or diffuse vascular disease.²⁹⁻³³ In such cases electrocardiographic changes may be the clue to the developing disease. Therefore, it can be seen that, useful as this technic is in the diagnosis of rheumatic fever, caution is necessary because of the possibility that nonspecific changes in the tracings may occur.

Many drugs may alter the form of the electrocardiogram. For a detailed enumeration of the abnormalities that may follow drug administration the reader is referred to the table in the text of Graybiel and White.³⁴

MULTIPLE PRECORDIAL LEADS

Electrocardiography has to some extent developed the hard way. The three standard leads were introduced first, and for years electrocardiographic interpretation was based on analyses of these leads alone. The standard leads, however, are complex in that they represent the difference between the electrical potentials at two points of the body remote from the heart — for example, Lead I is the difference be-

tween the left arm and the right arm. Hence, the interpretation of such records is not simple, although it is made easier by the assumptions implicit in the Einthoven triangle hypothesis. Unipolar leads that register the potential at one point and in which the second or indifferent electrode is at zero potential offer many advantages. Precordial and other chest leads, although not strictly unipolar, at least approach that situation. By the taking of such records at numerous points on the surface of the chest (and also on occasion from the esophagus), more exact information may be elicited regarding the presence and localization of cardiac lesions than can be obtained from the standard leads. A committee of the American Heart Association³⁵ has recognized the value of such multiple precordial leads by recommending that they be taken, as suggested by Wilson, at six points across the chest. If it is not feasible to take the six leads, the committee recommends that at least three — for example, C_1 , C_2 and C_3 — be obtained, some workers prefer C_1 , C_4 and C_5 . There is no agreement about which indifferent electrode is the best — that in the right arm, the left leg, the Wilson central terminal, the right scapular and so forth. Most authorities, however, accept the central terminal electrode of Wilson³⁶ as the one that most nearly approaches zero potential throughout the cardiac cycle.^{2, 3, 36-39} Wolferth,⁴⁰ who does not accept the validity of the Einthoven triangle hypothesis, disagrees.

In general, what type of information do multiple precordial leads furnish that cannot be gained as satisfactorily from the standard leads in addition to a single apical lead with which doctors are much more familiar? Their chief value is, of course, in the diagnosis of the presence and extent of anterior myocardial infarction. The earliest evidence of this condition may appear in the leads over the right side of the precordium and may continue to be limited to this area.^{2, 41} The findings in these leads may permit a definite diagnosis that might be missed altogether or could only be suspected from the standard leads or a single apical lead.

Multiple precordial leads are also useful in diagnosing bundle-branch block, particularly incomplete or atypical patterns.^{2, 3} In such leads there is a delay in the activation of the ventricle on the side of the block that will be registered by broad, notched or bifid R waves in the precordial leads over the ventricle on the blocked side.

Some assistance in the diagnosis of ventricular hypertrophy can also be obtained from multiple precordial leads.² The patterns seen in the standard leads may be confused with those in bundle-branch block or in normal hearts showing axis deviation, or the picture may be complicated by a combination of abnormalities. In normal hearts, even with axis deviation, the precordial leads are normal. With hypertrophy, on the other hand, the R wave is frequently unusually high in the leads taken over the

enlarged ventricle, with a small S wave, whereas the inverse pattern is found over the opposite side.

When a combination of abnormalities is present, such as myocardial infarction in addition to bundle-branch block or ventricular hypertrophy, and in other situations in which the standard leads are confusing, multiple precordial leads often enable a definite diagnosis to be made.^{2, 3}

UNIPOLAR EXTREMITY LEADS

Since the introduction of unipolar extremity leads⁴² and the extensive studies of Goldberger⁴³⁻⁴⁵ on this subject, there has been a gradually increasing appreciation of their clinical value. Such leads are of considerable assistance in judging the position of the heart in the thoracic cavity.² It has been shown that extremity leads register predominantly electrical potentials from the surface of the heart nearest them. Thus, the right-arm lead is usually negative, since facing it are the great valvular orifices, which tend to convey the potential of the ventricular cavities. The patterns of the left-leg and left-arm leads will resemble those found in precordial leads over the right or left ventricle, depending on whether the heart lies transversely or vertically. Occasionally, confusing patterns are present in the standard limb and precordial leads, as in anterior myocardial infarction with changes in Lead 3. In such cases the position of the heart may be responsible, and help may be obtained from unipolar extremity leads.

Extremity leads may also be of value in the diagnosis of posterior myocardial infarction when the standard leads are equivocal and the precordial leads are normal, and in other conditions in which a prominent Q_2 is present that may or may not represent heart disease, as mentioned below. Goldberger⁴⁴ has discussed their usefulness at considerable length.

DEEP Q_2 PATTERN

It is often of considerable practical importance to know whether variants seen in the standard leads are due to shifts in the electrical axis of the heart or to pathologic changes. This is especially true with the so-called "deep Q_2 " pattern, which may be a normal variant seen in transversely lying hearts or the only sign of recent or old posterior myocardial infarction. Esophageal leads most readily give the answer,⁴⁷ but such leads are often impracticable.

Pardee,⁴⁸ who originally pointed out the significance of the deep Q_2 pattern, stated that for such a wave to have a pathological import, it must have an amplitude at least 25 per cent as great as that of the largest QRS complex, and he also noted that in normal persons it tended to diminish with descent of the diaphragm. Lyle⁴⁹ observed that the disappearance of Q_2 on inspiration is proof that it is positional, although the converse does not hold. Ungerleider⁵⁰ did not agree with Lyle. Lyle also found that unipolar extremity leads were helpful in evaluating the size of the true Q wave. Myers and

Oren⁵¹ employed the left-leg lead in helping to distinguish between abnormal and normal Q_2 patterns, and found that when Q_{LL} had 25 per cent or more of the amplitude of R_{LL} a diagnosis of posterior infarction could be suspected. Goldberger,⁵² in an extensive article on the differentiation of normal from abnormal Q waves, came to the conclusion that posterior infarction was usually present if the Q_{LL} was 40 per cent or more of the entire QRS complex or 60 per cent of R_{LL} and was 0.04 second or more in duration, in association with a downward T wave and provided the QRS_{LL} pattern was not of the QS or W type. Ungerleider,⁵⁰ in a recent review of 1355 cases found that one or more of the following abnormalities were present in 94 per cent of cases with a deep Q_2 due to coronary disease, as compared to only 24 per cent of normal subjects: weight less than 5 per cent overweight, absence of S_1 , Q_2 more than 1 mm in depth, T_2 less than 1 mm tall, Q_2 of 0.04 second or more in duration, Q_2 of 75 per cent or more of the tallest R wave in the limb leads, and deep inversion of T_2 , exceeding 25 mm. Ungerleider was of the opinion that there is no need to employ unipolar leads in routine electrocardiography. Nyboer⁵³ took exception to these criteria, since he found them present in a substantial percentage of normal persons, especially those with horizontally lying hearts. He suggested that two or more of these impairments be required in the evaluation of the Q_2 and furthermore that chest and other exploratory leads may be required.

MAIN DEFLECTION DOWNWARD IN ALL STANDARD LEADS

Goldberger⁵⁴ has discussed the possible causes of electrocardiograms in which the main ventricular deflections are downward in the three standard leads. These are as follows: marked right-axis deviation, anterior infarction combined with marked left-axis deviation, posterior infarction combined with marked right-axis deviation, and combined anterior and posterior infarction. The last three of these show characteristic Q waves, which, in distinction to the S waves of axis deviation, help to distinguish them. Assistance may also be obtained from unipolar extremity leads.

ATYPICAL MYOCARDIAL INFARCTION AND THE ENDOCARDIAL ELECTROCARDIOGRAM

In 1938 Wood, Wolferth and Bellet⁵⁵ described an electrocardiographic pattern present in infarction of the lateral wall of the left ventricle, consisting of depression of the RST segments in Lead 4 and usually in Leads 1 and 2. Thomson and Feil⁵⁶ found 19 cases of lateral infarction in 136 cases examined at autopsy. Nine were recent, and in 4 the pattern described above was present. In this connection attention should be called to an experimental study by Wolferth et al.⁵⁷ on positive and negative displacements of the RST segments in which positive displacements are classified as primary because they

occur as the result of abnormal current flow originating in close relation with the exploring electrode, whereas negative displacements are secondary because they result from the abnormality originating in other parts of the ventricle. The negative RST segments may occur when there is involvement extending to the epicardial surface at a point away from the exploring electrode, as in lateral infarction, or when the lesion is confined to the endocardial aspects of the ventricular wall, even when this underlies the exploring electrode. Bayley⁵⁸ has cited a case in which injury was confined to the endocardial surface of the left ventricle that showed RST depression, and he, like the others, mentioned that such findings are seen in myocarditis, atypical myocardial infarction and angina pectoris. In two recent reports electrocardiograms were obtained on human beings with the exploring electrode introduced into the auricular and ventricular cavities by means of cardiac catheterization.^{59, 60} The findings confirmed experimental work on animals regarding the nature of the endocardial electrocardiogram.

Pardee and Goldenberg⁶¹ found that infarctions of the anterior wall of the left ventricle without subepicardial necrosis had atypical patterns that might resemble those described above in lateral infarctions. The typical changes in the ST segment and T wave occurred most frequently when the septum was involved, with or without necrosis of the wall of the ventricle itself.

When negative displacement of the ST segment occurs and myocardial infarction is suspected clinically, the injury may be either limited to the endocardial surface or remote from the exploring electrodes, as in lateral infarction. Help in differentiating the two may be gained at times by means of the use of precordial leads high in the chest, which may show positive displacements of the ST segment and typical changes in the QRS complex.⁶²

VENTRICULAR HYPERTROPHY

Another problem that vexes electrocardiographers is the determination of early degrees of ventricular hypertrophy. It is admitted that the electrocardiogram frequently gives evidence of left ventricular hypertrophy in patients with hypertension or other conditions producing left ventricular strain earlier than x-ray or other clinical measurements, but borderline cases are difficult to evaluate, since left-axis deviation is often present with normal hearts and left ventricular hypertrophy may exist with a normal axis. Indeed, in its early stages, the left axis that is usually present is probably due to the fact that the majority of such hearts lie transversely.

Mention was made above of the help to be gained from multiple precordial leads. Various investigators have laid down criteria for the diagnosis of left ventricular hypertrophy. Thus, Gubner and

Ungerleider⁶³ stated that left ventricular enlargement can be considered to be present when left-axis deviation occurs with any of the following when R_1 plus S_1 equals 25 mm or more, when there is any depression of ST_1 , even as slight as 0.5 mm, and when T_1 is less than 1.0 mm in height. And they further state that left-axis deviation is not a necessarily integral part of the pattern of left ventricular hypertrophy. White and his associates⁶⁴⁻⁶⁶ have traced the development of the electrocardiographic pattern in patients with hypertension and compared its frequent regression after lumbodorsal sympathectomy with the lack of improvement in patients treated in other ways. They reported findings in the limb leads similar to those mentioned above. In addition, they noted that half their cases showed abnormal T waves in Leads CF_4 and CF_5 , and in 24 per cent high voltage of the precordial QRS complexes existed.

ARRHYTHMIAS

Decherd, Ruskin and Brindley⁶⁷ cited a case showing interatrial block — a rare finding. A similar case has recently been seen at the Boston City Hospital.⁶⁸

Parsonnet et al⁶⁹ have published an elaborate classification of bigeminal rhythm in which twenty-nine mechanisms that may produce this phenomenon are described.

That cardiac arrhythmias may follow operations on the chest is becoming increasingly appreciated.⁷⁰⁻⁷² They may develop in connection with operation on the pleura, the lung or the heart. These arrhythmias may take the form of auricular fibrillation, flutter, frequent premature auricular beats, wandering pacemaker or nodal rhythm. They may occur during the operation or may be delayed for some days, and may be associated with the development of pulmonary infarction.

Evans⁷³ has advanced the theory that paroxysmal auricular tachycardia and flutter are the same, and that cases usually diagnosed as paroxysmal tachycardia have a 2:1 auriculoventricular block. Decherd, Ruskin and Herrmann⁷⁴ have, however, concluded from a study of momentary atrial electrical axes that in supraventricular tachycardia there is a single ectopic focus rather than a circus movement, as in auricular flutter and fibrillation.

SUMMARY

A résumé of certain recent developments in the field of electrocardiography is presented. In particular, electrocardiographic abnormalities in persons without organic heart disease, multiple precordial and unipolar extremity leads, atypical myocardial infarction, the deep Q_1 pattern and ventricular hypertrophy are discussed.

MASSACHUSETTS MEDICAL SOCIETY

PROCEEDINGS OF THE COUNCIL

Stated Meeting, February 5, 1947

A STATED meeting of the Council of the Massachusetts Medical Society was called to order by the president, Dr Dwight O'Hara, on February 5, 1947, at 10 30 a m in John Ware Hall, 8 Fenway, Boston, Massachusetts. Two hundred and one councilors were present (Appendix No 1)

The President announced that the secretary, Dr Michael A Tighe, was absent because of illness. He expressed a wish for his speedy recovery. The President announced that for the purpose of the meeting he appointed Dr Robert N Nye as acting secretary. This appointment was confirmed by the vote of the Council. The Acting Secretary presented the record of the Council meeting held on October 2, 1946, as published in the *New England Journal of Medicine*, issue of December 12, 1946. He moved its adoption. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

COMMITTEE REPORTS

Executive Committee

This report (Appendix No 2) was presented by the Acting Secretary, who moved its acceptance. This motion was seconded, and it was so ordered by vote of the Council.

Committee on Arrangements

This report, which was submitted by the chairman, Dr Sidney C Wiggan, Suffolk, was as follows:

The committee has been active since the October meeting of the Council. We have held a number of meetings, one of which was held jointly with representatives from the various sections.

From that meeting, we received many suggestions as to what topics and what speakers we should have on our program next May, and we are now in the process of arranging the program, which we can promise will be an interesting one.

The 1947 meeting will run for a full three days, instead of two and a half as last year, and this extra half-day will be given over to a program which will be devoted to a discussion of the accomplishments of the Massachusetts Medical Society in meeting the costs of sickness.

Last year, the Committee on Arrangements, under Dr Roy J Heffernan, showed a profit of \$5200. We may not be able to do quite so well this year as the Hotel Statler has increased our rental by 50 per cent and also decreased the number of exhibit booths that we may sell. However, Mr Boyd advises us that he has already sold all available booths, and we are certain we can show a substantial profit in 1947.

Owing to the increased length of the meeting, we have been able to set aside one evening exclusively for the Shattuck Lecture, instead of running it in with a general session, as we have had to do in recent years.

The committee would appreciate any suggestions from members of the Council regarding the program.

Dr Walter G Phippen, Essex South, moved the adoption of the report. This motion was seconded, and it was so ordered by vote of the Council.

Committee on Publications

This report (Appendix No 3) was offered by Dr Richard M Smith, Suffolk, chairman. Dr Smith called the Council's attention to the fact that this report contained three recommendations.

The first was that an appropriation of \$5000 be set aside on which the *New England Journal of Medicine* may draw if it becomes necessary. He moved the adoption of this recommendation. This motion was seconded, and it was so ordered by vote of the Council.

The second was that a directory of the officers and fellows of the Society be published in 1947. He moved the adoption of this recommendation. The motion was seconded, and it was so ordered by vote of the Council.

The third was that the advisability of the Society's setting up a retirement plan for its full-time employees be referred to a committee of the Society, either a special committee or an existing committee, according to the desires of the President and that if the adoption of such a scheme seems desirable a specific retirement plan be presented to the Council, subject to the approval of the Committee on Finance, if the matter was not referred to said committee. Dr Smith moved the adoption of this recommendation. This motion was seconded, and it was so ordered by vote of the Council, after the President had announced that the recommendation was approved by the Executive Committee.

Dr Smith announced that Dr William Dock, Director of Medicine, Long Island College of Medicine, Brooklyn, will deliver the 1947 Shattuck Lecture.

Dr Smith moved the adoption of the report as a whole. This motion was seconded, and it was so ordered by vote of the Council.

Committee on Public Relations

This report, which was presented by Dr Milton J Quinn, Middlesex East, a member of the committee, was as follows:

The Committee on Public Relations recommends to the Council that the committee be authorized to establish a speakers' bureau.

The Committee on Public Relations is not yet ready to report on the subject of a women's auxiliary to the Massachusetts Medical Society. The progress in this direction is that the committee has requested each member of the committee to canvass his district and report at the next meeting of the Public Relations Committee the sentiment in that district.

Dr Quinn moved the acceptance of the report. This motion was seconded by a councilor, and it was so ordered by vote of the Council. Dr Quinn pointed

out that this report contained one recommendation, namely, that the Committee on Public Relations be authorized to establish a speakers' bureau. He moved the adoption of this recommendation. This motion was seconded by Dr Phippen.

Dr Reginald Fitz raised the question whether or not the establishment of a speakers' bureau under the proposed auspices might hamper the Director of Medical Information and Education. The President said that this matter was brought to the attention of the Committee on Public Relations by the Secretary, who was being constantly called on to provide speakers for lay groups. He added that the Secretary found it difficult to obtain such speakers and expressed the thought that this means of valuable public approach should be on a sounder basis than heretofore existed. He added that the Committee on Public Relations agreed that a speakers' bureau should be set up, that the participating speakers in this bureau should come from all over the state and that this was an activity which belonged particularly to the committee. He said that the possibility of conflict with the newly proposed office had not occurred. In this connection he asked the Acting Secretary to read that part of the Executive Committee's report which had to do with this matter. The acting secretary said that the Executive Committee approved of the recommendation. He read the following from the committee's report:

The Committee on Public Relations asks the privilege of organizing this movement in the Society. It would make its selection of speakers from all parts of the state. The Executive Committee also believes that by adopting this recommendation the Council would give at least some direction to the office of the Director of Medical Information and Education and that this office might as one of its duties, work with and under the direction of the Committee on Public Relations in setting up and supervising the bureau called for in this recommendation.

Dr Frank R. Ober, Suffolk, asked if it would not be a good idea to have the bureau set up under the direction of the Director of Medical Information and Education. At this point, Dr Ober moved as an amendment to the recommendation that when and if a speakers' bureau is established it be organized by the Director of Medical Information and Education when and if such a director is elected. This amendment was seconded, and it was so ordered by vote of the Council. It was moved and seconded that a speakers' bureau be established. It was so ordered by vote of the Council.

Committee on Legislation

This report, which is as follows, was presented by Dr David L. Belding, Norfolk South, chairman:

The Committee on Legislation submits only a brief report of progress, since its activities do not begin until the Massachusetts Legislature convenes.

The first meeting of the committee was held on October 16, 1946 for the purpose of organization, since two thirds of its members were newly elected. At this meeting co-chairmen and a secretary were elected, special powers

were delegated to a small executive subcommittee, Mr Charles J. Dunn was appointed legislative counsel, the budget for the coming year was drawn up, and an analysis of the Taft Bill (S 2145) by the Subcommittee on National Legislation was approved and forwarded to the Council on Medical Service of the American Medical Association. The committee was represented on October 23, 1946, at a general conference on public-health legislation sponsored by the Massachusetts Central Health Council.

Dr Belding presented a supplementary report in which he said that his committee had examined and passed on thirty-five bills that had been introduced in the Legislature. He said that the bills which were opposed by the committee fell largely in one of three categories — those that would lower the standards of medical practice, those that would interfere with the freedom of medical research and those that would unfavorably affect the high standards at present maintained by our hospitals. He added that the Chiropractors' Bill was an example of the first, the Antivivisection Bill of the second and the bills that would throw open the doors of all hospitals to every licensed practitioner of medicine irrespective of his qualifications, of the third. Dr Belding moved the adoption of the report. This motion was seconded and it was so ordered by vote of the Council.

Committee on Finance

This report (Appendix No 4) was offered by Dr Robert W. Buck, Suffolk, chairman. He pointed out that the report was purely informational. He moved its adoption. This motion was seconded, and it was so ordered by vote of the Council. Dr Buck next presented the budget for the year 1947 (Appendix No 5). He moved its adoption. This motion was seconded, and it was so ordered by vote of the Council.

Committee on Public Health

This report (Appendix No 6) was presented by Dr Roy J. Ward, Worcester, chairman. He moved its acceptance. This motion was seconded, and it was so ordered by vote of the Council.

Dr Ward said his report contained several recommendations, the first of which was that the Council authorize the President to appoint a subcommittee of three to act as liaison between the Society and the State Department of Mental Health. He moved the adoption of this recommendation. This motion was seconded. The president reported that the Executive Committee approved of the recommendation. It was adopted by vote of the Council.

Dr Ward moved that the Council adopt the recommendations contained in the report of the Subcommittee on School Health. This motion was not seconded. The President said that this portion of the report of the Committee on Public Health provoked a good deal of discussion in the Executive Committee. He asked the Acting Secretary to read that part of the report of the Executive

Committee which relates to this subject. The latter read as follows:

In reviewing this report the Executive Committee gave first consideration to that part of the report submitted by the Subcommittee on School Health. The discussion indicated that this subcommittee came into being as the result of a mandate of the Council which was motivated by a letter that Dr. Fitz received from a committee of school executives asking that the Massachusetts Medical Society set up a committee that would study ways and means of improving medical services in schools. The Executive Committee notes that the subcommittee's principal recommendation is as follows: "To establish an effective liaison between representatives of the Massachusetts Medical Society and education officials at both state and local levels." The Executive Committee is in support of this proposal.

The Executive Committee notes that the subcommittee would activate this idea by (a) having the Massachusetts Medical Society appoint an over-all committee on school medical services and (b) having each district society appoint a local committee on school medical services, it being understood that each district would apply this principle according to the needs of the individual district.

With regard to "a," the Executive Committee recommends that the word "over-all" be deleted and that the word "advisory" be substituted. The Executive Committee is impelled to this action because it believes that the latter word more clearly describes the function of such a committee and the limitations that should govern its activities.

With regard to "b," the Executive Committee, in carrying out the same idea, recommends that the word "advisory" be placed between the word "local" and the word "committee." The Executive Committee also recommends the deletion of the following language, "it being understood that each district will apply this principle according to the needs of the individual district." The Executive Committee is impelled to this action by reason of the fact that it regards these lines as redundant.

The Acting secretary moved the adoption of the first recommendation of the Subcommittee on Public Health, with "a" and "b" as amended by the Executive Committee. This motion was seconded. Dr. Elmer S. Bagnall, Essex North, was recognized. He disapproved of that recommendation of the Executive Committee which would delete as redundant the following language, "it being understood that each district will apply this principle according to the needs of the individual district." He said that he was responsible for this language and that it was purposely used so as to permit the district committees to organize their work in a manner which would suit their individual needs. He moved as an amendment to the motion that this language be permitted to stand. This was seconded. The recommendation of the Executive Committee, subject to Dr. Bagnall's amendment, was adopted by vote of the Council.

The President called the Council's attention to the fact that this report of the Subcommittee on School Health contained thirteen additional recommendations. He said that the Executive Committee recommended that these thirteen recommendations be referred to the advisory committee heretofore authorized for further study and elucidation and that this committee's attention be directed particularly to Recommendations 11 and 12 to the end that the language of these latter recommenda-

tions be changed so as to provide that the interpretation of physical findings shall continue to be the function of the physician alone and not be shared with the school nurse. It was moved and seconded that the recommendations of the Executive Committee with regard to this part of the report be adopted. It was so ordered by vote of the Council.

The President next referred to that part of the report of the Committee on Public Health which referred to public-health personnel. This part imperatively recommended that aggressive support of Dr. Getting's proposals be given and that the aid of the Committee on Legislation be obtained in expediting his program. The report outlined these proposals as follows:

- (a) To raise the salary level of the professional personnel engaged in public health on a state and local basis
- (b) To institute a sanitary code
- (c) To provide for subsidization of local health departments when, as and if they meet standards as to personnel and program content
- (d) To promote town unions of adequate size (at least 20,000 population) to support a modern public-health and school-health program at a per capita cost of \$1.50 to \$2.50 exclusive of tuberculosis and communicable-disease control and exclusive of garbage collection

The president asked that that part of the Executive Committee report dealing with this subject be read. The Acting Secretary read from the report as follows:

The Executive Committee notes that that part of the report dealing with public-health personnel, if approved by the Council, would commit the Society in a manner in which it should not be committed. It therefore recommends that the Council take no action on this matter on the grounds that the subject is beyond the scope of the Society.

Dr. Roy J. Ward was recognized. He said that he vigorously objected to the conclusion arrived at by the Executive Committee in this matter. The State Department of Public Health, he added, established many years ago largely through the influence of this society, was in danger of losing its efficiency, if not actually breaking down, through its inability to pay salaries to its personnel in keeping with those prevailing in other states or in industry. He pointed out that other states, notably New Hampshire, already had a sanitary code. He said that the recommendations of the Committee on Public Health were in accordance with a request of the American Medical Association. Finally he expressed the thought that the Executive Committee could not have been cognizant of all the facts on this subject when it arrived at its conclusions. Dr. Ward moved the adoption of the recommendations contained in that part of the report of the Committee on Public Health dealing with the subject under discussion. This motion was seconded.

Dr. Elmer S. Bagnall, in speaking in support of the motion, quoted Dr. Lewis H. Bauer, trustee of the American Medical Association, as follows:

Training of public-health officials is important, and when they are trained they should be adequately compensated. At the present time many of these officials do not receive the income of men engaged in private practice or often in other fields of medicine. The implementing of this second point is by means of legislation.

Dr Fremont-Smith, Suffolk, expressed the thought that the figures \$1 50 and \$2 50 appearing in proposal "d" should be eliminated, it being out of place for the Massachusetts Medical Society to go into such financial details. Other than this he thought the Society should support the proposals.

Dr Donald Munro, Suffolk, said that, while he favored the support of these proposals, such support implied an obligation on the Society's part to say whence the money necessary to carrying them through was coming. He expressed the thought that the Society was not in a position to meet such an obligation.

Dr Lester M. Felton, Worcester, said that the councilors of the Worcester District Medical Society, at a meeting held previous to this one, declared themselves as opposed to the implied recommendation of the Committee on Public Health. He added that it was a bad precedent to create and that if it were created, medical personnel employed by the state generally might request and reasonably expect similar backing.

Dr Reginald Fitz, Suffolk, asked if there were bills along the lines of discussion now before the General Court and if so what was the opinion of the Committee on Legislation with regard to them.

Dr Belding said that there were certain bills of this character before the Legislature. He mentioned a bill that would set up a sanitary code and said that his committee had favored it. He added that there were innumerable other bills that were largely departmental in character. The Committee on Legislation had taken no action on these bills, although it was in sympathy with the principles contained in many of them, because it believed that it was unwise to spread its activities out too thinly lest its effectiveness and strength be correspondingly weakened.

Dr Richard M. Smith said he would like to endorse what Dr Ward had said and to emphasize the fact that the Commonwealth cannot have good public-health service unless those who render the service are adequately compensated.

Dr Vlado A. Getting, Middlesex South, was recognized and spoke as follows:

I should like to state that I am appearing here not for any personal gain but in the interests of the people of the Commonwealth. In the first place, any increases in salaries that are contemplated would amount to less than 0.5 per cent of the total state budget. It is the duty of the Legislature, the Great and Honorable General Court of Massachusetts, to find ways of raising money. It is the duty of the medical profession to give leadership and to give guidance to the General Court in matters of public health, and it is not the duty of the Society or of the Department of Public Health to tell the General Court how to arrange its tax structure.

I should like to call the attention of members of the Council to the Society's bulletin *Digest, By-Laws, Code of Ethics and Medical Deference Act of the Massachusetts Medical Society*. There are many references to public health, but I shall refer to only one. On page 38, Chapter IV, Section 1, it states "Physicians, as good citizens, and because their professional training specially qualifies them to render this service, should give advice concerning the public health of the community. They should bear their full part in enforcing its laws and sustaining the institutions that advance the interests of humanity. They should co-operate especially with the proper authorities in the administration of sanitary laws and regulations."

In the Department of Public Health there are at present fifty vacancies. The average salary for a doctor in this department is \$4600, a level that is thirty-ninth on the scale of all the states in the Union. And if you add the territories and cities, we would be about fiftieth. There was a time when we were leading among the state health departments in this country. We are now very much of a borderline state. We have only one physician in the Division of Communicable Diseases, and only one in the Division of Venereal Diseases. With only one exception there is not a medical division or department in which there is a qualified assistant director ready to take over.

The situation is tragic. I have advised the officers of the Society on numerous occasions of the needs of the Department. We have referred to you from time to time our policies and procedures for your advice and endorsement, and have obtained them. I have been informed by the officers from time to time that the co-operation between the Department and the Society is the greatest it ever has been. Sympathy, however, never saved a patient's life. The Society takes pride in having created the Department of Health. It is a dying department, and one that needs prescribing. It needs help.

So far as legislation is concerned, only one bill has been introduced this year, and that has to do with the sanitary code. The help that is needed is not in the appearance formally before a legislative committee, but an action in conference with members of the Ways and Means Committee and with the Governor and his advisers. It is my conviction that unless we can obtain qualified men and unless we can prevent the further depletion of our doctors, we will be faced with a truly critical situation.

The only physicians whom we have been able to employ in the last two or three years are men who have a retirement from the Army or Navy or women who have families and can work part time.

I entered the Department of Public Health in 1938, and to the best of my recollection, I am the last physician to have entered that department who had had any training in public health and who wished to make a professional career of public health. That is how bad the situation is.

The programs that are listed here are, as a matter of fact, in accordance not only with the code of the Society but also with our code of ethics, yours and mine. They are in accord with the program that has been put out by the American Medical Association, which the Executive Committee recommends that you accept, because that is contained in the first portion of this report and reads as follows: "That the trustees of American Medical Association be urged to use all appropriate resources and influences of the Association to the end that complete coverage of the Nation's area and population by local, county, district or regional full-time modern health services be achieved."

I have only one further thing to say. If we lose momentum, the Department becomes impotent, there is only one other thing to do and that is hire substandard men — graduates of unapproved schools and refugees.

No one knows what is going to happen in Washington, but if the Taft Bill or any other similar bill is passed, the Department of Public Health is going to be administering agent here. And if any of you think that even now the Department does not have a truly significant influence on medical practice in Massachusetts, I invite you to come up there for a day and view some of the things that go on.

We want to work with the medical profession. We need your support. We cannot have good public health unless the doctors in Massachusetts support the Department of Public Health.

Committee which relates to this subject. The latter read as follows:

In reviewing this report the Executive Committee gave first consideration to that part of the report submitted by the Subcommittee on School Health. The discussion indicated that this subcommittee came into being as the result of a mandate of the Council which was motivated by a letter that Dr. Fitz received from a committee of school executives asking that the Massachusetts Medical Society set up a committee that would study ways and means of improving medical services in schools. The Executive Committee notes that the subcommittee's principal recommendation is as follows: "To establish an effective liaison between representatives of the Massachusetts Medical Society and education officials at both state and local levels." The Executive Committee is in support of this proposal.

The Executive Committee notes that the subcommittee would activate this idea by (a) having the Massachusetts Medical Society appoint an over-all committee on school medical services and (b) having each district society appoint a local committee on school medical services, it being understood that each district would apply this principle according to the needs of the individual district.

With regard to "a," the Executive Committee recommends that the word "over-all" be deleted and that the word "advisory" be substituted. The Executive Committee is impelled to this action because it believes that the latter word more clearly describes the function of such a committee and the limitations that should govern its activities.

With regard to "b," the Executive Committee, in carrying out the same idea, recommends that the word "advisory" be placed between the word "local" and the word "committee." The Executive Committee also recommends the deletion of the following language, "it being understood that each district will apply this principle according to the needs of the individual district." The Executive Committee is impelled to this action by reason of the fact that it regards these lines as redundant.

The Acting secretary moved the adoption of the first recommendation of the Subcommittee on Public Health, with "a" and "b" as amended by the Executive Committee. This motion was seconded. Dr. Elmer S. Bagnall, Essex North, was recognized. He disapproved of that recommendation of the Executive Committee which would delete as redundant the following language, "it being understood that each district will apply this principle according to the needs of the individual district." He said that he was responsible for this language and that it was purposely used so as to permit the district committees to organize their work in a manner which would suit their individual needs. He moved as an amendment to the motion that this language be permitted to stand. This was seconded. The recommendation of the Executive Committee, subject to Dr. Bagnall's amendment, was adopted by vote of the Council.

The President called the Council's attention to the fact that this report of the Subcommittee on School Health contained thirteen additional recommendations. He said that the Executive Committee recommended that these thirteen recommendations be referred to the advisory committee heretofore authorized for further study and elucidation and that this committee's attention be directed particularly to Recommendations 11 and 12 to the end that the language of these latter recommenda-

tions be changed so as to provide that the interpretation of physical findings shall continue to be the function of the physician alone and not be shared with the school nurse. It was moved and seconded that the recommendations of the Executive Committee with regard to this part of the report be adopted. It was so ordered by vote of the Council.

The President next referred to that part of the report of the Committee on Public Health which referred to public-health personnel. This part imperatively recommended that aggressive support of Dr. Gettling's proposals be given and that the aid of the Committee on Legislation be obtained in expediting his program. The report outlined these proposals as follows:

- (a) To raise the salary level of the professional personnel engaged in public health on a state and local basis
- (b) To institute a sanitary code
- (c) To provide for subsidization of local health departments when, as and if they meet standards as to personnel and program content
- (d) To promote town unions of adequate size (at least 20,000 population) to support a modern public-health and school-health program at a per capita cost of \$1.50 to \$2.50 exclusive of tuberculosis and communicable-disease control and exclusive of garbage collection

The president asked that that part of the Executive Committee report dealing with this subject be read. The Acting Secretary read from the report as follows:

The Executive Committee notes that that part of the report dealing with public-health personnel, if approved by the Council, would commit the Society in a manner in which it should not be committed. It therefore recommends that the Council take no action on this matter on the grounds that the subject is beyond the scope of the Society.

Dr. Roy J. Ward was recognized. He said that he vigorously objected to the conclusion arrived at by the Executive Committee in this matter. The State Department of Public Health, he added, established many years ago largely through the influence of this society, was in danger of losing its efficiency, if not actually breaking down, through its inability to pay salaries to its personnel in keeping with those prevailing in other states or in industry. He pointed out that other states, notably New Hampshire, already had a sanitary code. He said that the recommendations of the Committee on Public Health were in accordance with a request of the American Medical Association. Finally he expressed the thought that the Executive Committee could not have been cognizant of all the facts on this subject when it arrived at its conclusions. Dr. Ward moved the adoption of the recommendations contained in that part of the report of the Committee on Public Health dealing with the subject under discussion. This motion was seconded.

Dr. Elmer S. Bagnall, in speaking in support of the motion, quoted Dr. Lewis H. Bauer, trustee of the American Medical Association, as follows:

expressed the opinion that by setting up a board of trustees the Society would have a small group that would more or less run the organization. Dr Bearse went on to say that the Executive Committee was set up five years ago when the present by-laws were adopted. He added that even then the danger of such a group dominating the Society was thought of and that to prevent such a situation it was provided that no member of the Executive Committee could serve consecutively more than three years.

Dr Edward P. Bagg, Hampden, said that the only question before the Council was the creation of a committee to study this matter. He added that he believed that this recommendation of the Committee on Postwar Planning should prevail.

Dr Frank R. Ober said that he had served as the first chairman of the Executive Committee and that in the beginning this committee was not particularly effective but that this was due to the fact that the duties of the committee had not been defined. He said, however, that as time went on the value of the committee had been proved. Its activities had shortened the Council meetings, and at no time had the Council been a rubber stamp for it. By the same token he believed that the Council would not be a rubber stamp for a board of trustees were such a group set up in the Society. He also pointed out that the recommendation of the Committee on Postwar Planning merely called for a study of this subject.

Dr Root said that his committee, when it made this recommendation, did not have in mind the reducing or minimizing the function of any other committee now in existence. The purpose of the recommendation was simply to find some improved mechanism of meeting the new and varied problems that were continually presenting themselves.

The President said that the question came on the adoption of the recommendation of the Executive Committee and further defined the subject before the Council and asked it to vote on whether or not a special committee should be created to consider the advisability of setting up a board of trustees within the structure of the Massachusetts Medical Society. The Council voted not to establish such a committee.

Dr Root then moved that the Committee on Postwar Planning be discharged. This motion was seconded.

The President said that the Executive Committee in favoring the adoption of this motion also recommended that the discharge carry with it the expression of the Council's gratitude for a job well done and that this expression of gratitude be in a special manner directed toward the chairman, Dr Root, who had given so generously of his time and patience over a period of years. This motion was adopted by vote of the Council. The Council extended a rising vote of thanks to Dr Root and his committee.

Committee to Nominate a Director of Medical Information and Education

(Dr John F. Conlin asked to be excused while this part of the agenda was under consideration. The President granted his request.)

This report (Appendix No. 8) was presented to the Council by the secretary of the committee, Dr Elmer S. Bagnall. The President said that it contained several recommendations: first, that Dr John Francis Conlin be appointed Director of Medical Information and Education; second, that Dr Conlin's employment begin on July 1, 1947; third, that his compensation be at a rate of \$7500 per year, plus ordinary traveling expenses and appropriate vacation periods; that if his services are satisfactory and if he is satisfied with the work as it develops, he shall receive an increase of \$500 on January 1, 1948, and on each January 1 until his maximum salary of \$10,000 will be reached on January 1, 1952; and fourth, that legal counsel should be asked to draw up a written agreement which should embody these general terms, an understanding concerning the mutual termination of the agreement and provisions which will permit adjustments in salary should our national economy become subject to gross inflation.

All these recommendations of the committee were adopted without debate and by the unanimous vote of the Council.

Dr Carl Bearse was recognized. He commented on the fact that the Council had just created a position without any statement regarding the duties of this position. He moved that the Director of Medical Information and Education be assigned to the Office of the Secretary. Dr Donald Munro raised as a point of order that this motion constituted new business and was therefore out of order. The President declared the point of order well taken.

(At this point, Dr John F. Conlin, having returned to the meeting, was asked to stand. He was greeted with applause.)

Dr Ober moved that the committee report as a whole be accepted and that the committee be discharged with the thanks of the Council. This motion was seconded, and it was so ordered by vote of the Council.

Committee on Postgraduate Assembly

This report, which is as follows, was presented by the chairman, Dr Leroy E. Parkins, Suffolk.

The committee invited the other New England state medical societies to co-operate in presenting the New England Postgraduate Assembly; each society responded and appointed members to the Executive Committee. A Program Committee and other committees were appointed, and the Assembly was presented at the Hotel Bradford on October 30 and 31, 1946.

The attendance was as follows:

Maine	40-
New Hampshire	30
Vermont	16

The motion was adopted by vote of the Council

Committee on Postwar Planning

Dr Howard F Root, Suffolk, chairman, presented this report (Appendix No 7) Dr Root moved the acceptance of the report This motion was seconded, and it was so ordered by vote of the Council The report reviewed the accomplishments of the committee It indicated that the committee regarded its work as finished It expressed the belief that certain of its subcommittees should be continued as special committees. With the latter in mind, Dr Root moved that the Council authorize the creation of a special committee to be known as the Committee on Postgraduate Medical Education, that this committee consist of seven members to be appointed by the President subject to confirmation by the Council, and that the committee so appointed be charged with the direction of the Society's postgraduate educational program and its Bureau of Clinical Information, except as might be otherwise ordered by the Council This motion was seconded, and it was so ordered by vote of the Council

Dr Root moved that the Council authorize the creation of a special committee to be known as the Committee on Medical Economics, that this committee consist of five members to be appointed by the President subject to confirmation by the Council, and that the committee so appointed be charged with the study and direction of methods by which members of the Society might be informed regarding the economic status of medical practice now and in the future This motion was seconded, and it was so ordered by vote of the Council

Dr Root moved that the Council authorize the creation of a special committee to be known as the Committee on Veterans Affairs and that the members of this committee be appointed by the President subject to confirmation by the Council This motion was seconded, and it was so ordered by vote of the Council

Dr Root moved that the Council authorize the creation of a special committee of five members to be appointed by the President, subject to confirmation by the Council, to consider the advisability of setting up a board of trustees within the structure of the Massachusetts Medical Society and that in the event that such a committee decides affirmatively in this matter it be further charged with recommending the duties of such a board of trustees and with the preparations of such amendment or amendments to the by-laws as might be necessary

The President said that the Executive Committee had concerned itself with this recommendation He asked the Acting Secretary to read that part of that committee's report which dealt with this subject The latter read as follows

The Executive Committee recommends that the Council disapprove this recommendation In the discussion attend-

ing this subject, it came out that the Executive Committee, consisting of one representative from each district in the Commonwealth, had been performing what might be regarded as the functions of a board of trustees, but that there was a feeling in the Committee on Postwar Planning that there was at times a lack of over-all policy due to the size of the Executive Committee and the shortness of time (three years) in which any single member might hold continuous office On the other hand it was emphasized in this discussion that there never had been any difficulty in getting the Executive Committee together even in emergency session and that a board of trustees might result in too centralized a government, which might affect unfavorably the democratic character of the Society and alienate the interests of the ordinary member The wisdom of setting up a board of trustees, which in the ordinary course of events might be expected to take over the functions now being satisfactorily performed by the Executive Committee, was seriously questioned It was pointed out that the recommendations did not actually propose that such a board of trustees be set up, but only that a committee be authorized to study this subject It was also pointed out that a board of trustees might be needed to give direction to the efforts of the Director of Medical Information and Education There were certain district societies that reported their councilors, as unanimously opposed to the proposal

The Acting Secretary moved the adoption of the recommendations of the Executive Committee. This motion was seconded

Dr Bagnall was recognized He said that he spoke as an ex-president He expressed the thought that only the individual who has served as president quite comprehends the whole prospective of the structure of the Society He said that there was need for a group in the Society to whom the President could look for advice with regard to policies He said that his experience as president led him to believe that the Executive Committee did not fill this function Theoretically, he said, the setup of the Executive Committee was excellent He said that it had not worked out because of the lack of interest which many of the members of the committee took in its proceedings He said that he did not necessarily favor a board of trustees with any great powers, what he did want was a policy committee with a continuity of interests and made up of faithful, self-sacrificing men with the service motive to whom the President could turn for advice He pointed out that the recommendation of the Committee on Postwar Planning simply asked for a committee to study this matter Dr Leroy E Parkins, Suffolk, seconded Dr Bagnall's remarks

Dr George L Schadt, Hampden, said that a board of trustees would make the necessity for an executive committee practically nil He said that presumably such a board might be made up of five or seven members He added that he did not like to see such power placed in a small group He thought that the answer to this whole difficulty might be had by reducing the size of the Council so that each member would represent one hundred members rather than twenty, as now prevails

Dr Carl Bearse, Norfolk, stated that he thought that the Society had done very well over the years without a board of trustees He added that as the Society is set up today it is truly democratic He

Second, that this rate become effective January 1, 1948, and

Third, that of the total dues, \$5 00 be earmarked for the use of the Boston Medical Library

Dr George L. Schadt, Hampden, moved the adoption of the first recommendation. This motion was seconded.

Dr William H. Blanchard, Suffolk, thought that by raising the dues the Society might lose certain of its members. In consequence of that he said that there was some question in his mind whether or not the raising of the dues would really provide the funds necessary to do the things set forth in the committee's report.

Dr Schadt said that in increasing the dues the individual member should think of this increase as enabling the Society to better serve the public rather than in terms of what additional benefits should accrue to him. He added that he was for the increase and that even if it were greater he would still support it.

Dr Hyman Morrison, Norfolk, asked if the committee had considered the point of view of the young man who had just graduated and of the man in declining years whose income is waning. The President replied that there was no mention of such in the report.

The first recommendation of the Executive Committee was adopted by vote of the Council.

The President said that the second recommendation of the Executive Committee, namely, that the new rate of dues become effective on January 1, 1948, was before the Council. Its adoption was moved and seconded. The motion was adopted by vote of the Council. The adoption of the third recommendation of the Executive Committee was moved and seconded.

Dr Phippen was recognized and spoke as follows:

I ask your indulgence to say a few words about the Boston Medical Library. It is an old institution, founded in 1805. It had many vicissitudes, and in 1872 the Massachusetts Medical Society, having a library of its own, suddenly decided that it did not need it and transferred its collection of books to the Boston Public Library.

This created one of our customary furores in the Society, and a lot of younger men started the Boston Medical Library, which began in Hamilton Place in 1875 and which has grown to this large establishment that we have today. It is now the third largest medical library in the country. It has nearly 200,000 books — probably over that now — and 135,000 pamphlets. It has a large collection of rare books.

The Boston Medical Library should fill a definite place in the profession of medicine, not only in Boston and in Massachusetts but also in all the New England states. It is one of the most important parts of the practice or of the profession of medicine.

I have often heard it said that those of you in the distant parts of the Commonwealth do not use the Library. That is not a fact. Every time you read one of the papers that are published in the *New England Journal of Medicine*, which have made the *Journal* what it is today, you are using the Library. All the bibliography for those papers comes out of this library. So every one of you use it.

A medical library occupies the same relation to the profession of medicine that a public library occupies to the citizens of a community. A lot of citizens in the community do not use the public library, and yet they pay for

it and they pay for it gladly, because they know it has to do with their educational development. The same thing is true of the Boston Medical Library. You ought to be glad and willing to help support the Library because of the good it does to the profession at large.

A survey of the Library made by Dr Fleming, of the Medical Library of Columbia University, in 1941 developed the fact that this library should be a real reference library, co-ordinating its activities with the libraries of the medical schools and with the libraries of the hospitals. And a committee that was formed to review that report so recommended. The trustees of the Library have tried hard to bring that about, but unfortunately it could not be done because of lack of funds. The Library depends for its income on certain gifts and bequests and on the income from its members. Many well intentioned people have given money to the Boston Medical Library, but unfortunately, a great deal of that money is earmarked for rare and unusual books. Therefore that money cannot be used for the running expenses of the Library. Every effort has been made by the Board of Trustees, particularly by Dr Cheever, to interest philanthropic organizations in the Library. Foundations have been approached to see if they would contribute funds, but they are not interested in an organization that is not a going concern.

The trouble with the Library is that it has outgrown its income. It has gone on successfully and wonderfully, really, with the amount of help that it has had, to give the service that it has given, but it does not by any means begin to give the service that it ought to give. When you come to think that here is a library worth a great deal of money, with 200,000 odd volumes of books, that is serviced by a director, a secretary and four employees only, you can understand why it cannot give service.

This library could give a tremendous amount more service than it gives at the present time if it had the proper income. The income of the Library today is only about \$30,000, and at that the yearly deficit is about \$1000 or a little more. With the income that the Massachusetts Medical Society could give us, we would be able to service the Library. We would be able to provide enough personnel to put the multitudes of books that line the corridors, the cellars, the attic and the garret on the shelves where they belong, and to provide sufficient help so that you could use these books when you wanted them.

The Library is educational. I want to call your attention to this painting [pointing to the picture behind the President's desk] by an anonymous donor, which has been redone and which was exhibited at the Ether Day Celebration of the Massachusetts General Hospital, it caused a great deal of interest to everybody. It is one of the educational features of the Library.

I shall be only too glad to answer questions as to the needs of the Library, but I can say frankly that, unless something is done to help the Library, it will go on functioning in this modest way — for how long I cannot tell. You are economists enough to know that if it spends \$1000 a year more than it earns with an annual income of only \$30,000 a year, it will not be long before the Library will have to close its doors.

All I can say is what Dr. Warren said on this occasion [again pointing to the picture], "Gentlemen, this is no humbug."

Dr Schadt asked the previous speakers that in the event that the recommendation before the Council were adopted whether the Library would devise some method by which physicians in the western and northern parts of Massachusetts would be sent such books as they may require. Dr Phippen answered in the affirmative.

Dr Bearse asked whether it would still be necessary for the Library to have its own membership and dues if the motion prevailed. Dr Phippen answered the question as follows:

Yes, it will be. Some of you may remember that a number of years ago an attempt was made to form an

Massachusetts	359
Rhode Island	21
Connecticut	22
	<hr/> 488
The income and expenses were as follows	
Receipts from exhibits	\$3,600 00
Receipts from registrations and tickets	3,202 45
	<hr/>
Total	\$6,802 45
Expenses	5,964 97
	<hr/>
Credit balance	\$837 48

This credit balance will offset deficits made in previous years. It also demonstrates that the Assembly can be self-supporting.

The Assembly Executive Committee recommends that the New England Postgraduate Assembly be continued as a permanent independent organization sponsored and supported by the New England state medical societies. It was suggested that a governing board be composed of officially appointed representatives from all the medical societies, each being allowed one representative for each one thousand members or fraction thereof (this is essentially the ratio of the current organization). Financial support, if necessary, would likewise be on a percentage basis.

The committee recommends that a committee be appointed to arrange an assembly in 1947 and that the Council approve of the setting up of an independent organization to be known as the New England Postgraduate Assembly.

Dr Parkins moved the acceptance of the report. The motion was seconded and it was so ordered by vote of the Council. Dr Parkins said that the report contained two recommendations, first, that a committee be appointed to arrange a postgraduate assembly in 1947. He moved the adoption of the first recommendation. This motion was seconded, and it was so ordered by vote of the Council. He said that the second recommendation requested the Council to approve the setting up of an independent organization to be known as the New England Postgraduate Assembly. He moved the adoption of this recommendation. This motion was seconded by a counselor.

The President said that the Executive Committee considered this and that inasmuch as the Council of the New England State Medical Societies was a going concern in which the Society was represented it thought that if the sponsorship of the postgraduate assembly was to pass from the Massachusetts Medical Society to New England it was desirable that it be assumed by this council as the only organization that is truly representative of New England as a whole. The President stated that at the time of the meeting of the Executive Committee, inasmuch as this subject had not been presented to the Council of the New England State Medical Societies, its viewpoint had not been ascertained. He added that it came to the committee's attention that this council was to meet on January 15. The Secretary, who is one of the representatives of the Society in this council, was instructed to ascertain its views in this matter. The President added that the Secretary had followed the instructions and that the viewpoint of the New England Council in

this matter was fully outlined in the report of the Executive Committee. He said that this report indicated that the New England Council would have to ascertain the view of the several individual state societies which it represents before it could express an opinion with regard to the proposition. The report indicated that this could not be done much before June 1 and that this would be too late to allow for the planning of an assembly in the fall of 1947. The President said that as a result of this the Secretary suggested that the Council approve the first recommendation, which it had already done, so as to provide for the continuation of the assembly, and lay the second on the table until such time as the Council of the New England State Medical Societies was ready to act.

Dr Frank R. Ober moved that the second recommendation be laid on the table. The motion was seconded by Dr. Walter G. Phippen, Essex South. It was so ordered by vote of the Council.

Committee to Study Increase in Assessment of Dues

This report (Appendix No. 9) was offered by the chairman, Dr. Frank R. Ober, Suffolk, who moved its acceptance. This motion was seconded, and it was so ordered by vote of the Council.

Dr. Ober said that in connection with an increase in dues the committee had considered certain functions of the Society which it ought to be, but was not, serving. He said that there was the matter of a retirement fund spoken of earlier in the meeting, as well as the care of widows and orphans of physicians who might find themselves in difficult circumstances. He said that the Vermont State Medical Society sets aside part of its annual dues for this purpose. Dr. Ober spoke of the Massachusetts Benevolent Society and the aid that it was giving to many. He said that thought should be given to the matter of combining in some way the efforts of this organization with those of the Massachusetts Medical Society. He said that the Boston Medical Library should be helped. He finally said that, although his committee offered no definite recommendations at this time, it was hoped that the Council would be thinking about the matter contained in the report. He said that the Executive Committee in its analysis of the report offered certain recommendations with regard to the matter of dues. He asked that these recommendations be read.

At the direction of the President, the Acting Secretary read from the report of the Executive Committee as follows:

With all these considerations in mind [referring to the Executive Committee's analysis of the report] the Executive Committee believes the membership dues should be increased. It also believes that out of this increase a certain allotment should be made to the Boston Medical Library. It therefore recommends:

First, that the Council set the membership dues at \$25.00 per year,

Dr Watkins moved its acceptance. This motion was seconded, and it was so ordered by vote of the Council.

Committee to Study Income Level for Blue Shield

This report, which is as follows, was presented by the chairman, Dr Charles F Wilinsky, Suffolk.

The committee has met to study the income level for Blue Shield subscribers in relation to eligibility for the Ward Plan.

It has considered this question carefully and has given justifiable and serious thought to the relation of income level for medical eligibility under the Blue Shield Plan as related to similar eligibility to Blue Cross Ward Plan Service.

The Blue Cross has recently given consideration to a change in income limitations for eligibility for its Ward Plan and has approved the following levels:

Single subscriber, no dependents	\$2 000
Subscriber and one dependent	2 500
Subscriber with more than one dependent	3,000

A canvass of our committee has resulted in accord and approval of the above-mentioned earning limits in relation to Blue Shield eligibility, and we so recommend the above schedule for the consideration of the Council.

The President said that the Executive Committee was much confused by this report and recommended that it be referred back to the committee for elucidation. He called on Dr Wilinsky to clarify it.

Dr Wilinsky said that this matter had been referred to his committee for the purpose of determining whether or not, in view of the higher cost of living, the worker earning \$2000 a year or the family whose total income was \$2500 was in as good a position to pay a supplementary fee to the surgeon as he was when the Blue Shield was established. He said his committee believed that they were not. Consequently, it recommended the following new schedule: that no supplementary fee should be paid to the surgeon by the person earning \$2000 or less, by the person with one dependent earning \$2500 or less, or by the person with more than one dependent earning \$3000 or less. Dr Wilinsky moved the adoption of the recommendation of his committee. This motion was seconded, and it was so ordered by vote of the Council.

Committee to Meet with General Hawley

In the absence of Dr McCarthy, the report was presented by the President. This report is as follows:

Your committee has been to Washington, has completed Part A of the Fee Schedule and has turned it over to the Massachusetts Medical Service, Blue Shield, to administer.

The President, by way of implementing this report, said that the contract between the Veterans Administration and the Blue Shield had been signed. He added that the contract was in accordance with all the votes of the Council as to fees. It was moved and seconded that the report be accepted. It was so ordered by vote of the Council.

Medical Advisory Committee to the Regional OPA

This report, which is as follows, was presented by the chairman, Dr Joseph Garland, Suffolk.

The Medical Advisory Committee to the OPA has nothing more to do now than to review an occasional sugar application. When sugar goes off rationing the committee can be reured and we will be glad of the chance.

It was moved and seconded that the report be accepted. It was so ordered by vote of the Council.

Committee on Industrial Health

This report, which is as follows, was offered by the chairman, Dr Daniel L. Lynch, Norfolk, as a report of progress.

At the present time the Committee on Industrial Health can submit only a report of progress as follows:

First, a survey is in progress to ascertain the names and connections of the physicians in Massachusetts who are actually engaged in industrial medicine, that is, physicians who have a definite connection with an industrial, mercantile or other establishment.

Second, we are taking steps to determine the number and connections of nurses who are employed in industrial, mercantile, business or similar establishments.

Third, we are taking steps to determine the number of nurses who have medical supervision and those who do not.

It is our hope that this survey will be well along by the February meeting.

He moved its adoption as such. The motion was seconded, and it was so ordered by vote of the Council.

APPOINTMENTS

The President made the following *ad interim* appointments:

To the Committee on Legislation

Dr Solomon L. Skvirsky, Norfolk

To the Committee on Cancer

Dr Shields Warren, Suffolk, *Chairman*

To the Committee on Veterans Affairs

Dr Edwin M. Mahoney, Hampden

Dr Charles A. Wheeler, Worcester North

It was moved and seconded that these appointments be confirmed. It was so ordered by vote of the Council.

NEW BUSINESS

Dr Augustus Thorndike, Suffolk, was recognized. He submitted the following resolution:

WHEREAS, The Fracture Committee of the American College of Surgeons has recommended the establishment of community rehabilitation centers in all states, and

WHEREAS, The National Service Fund of the Disabled American Veterans is sponsoring the establishment of a nonprofit organization in Boston to be called the Rehabilitation Center, on an outpatient service basis for patients in the terminal stages of convalescence, to which may be referred by doctors, by hospitals and by governmental and private agencies veteran and civilian patients with disabilities requiring medical evaluation and treatment, including physical therapy and occupational therapy, as well as evaluation for proper job placement at time of release, be it therefore

RESOLVED, That the Council authorize the president to refer to the appropriate committee or committees for study, with a report and a recommendation to be presented at the next meeting of the Council, the question whether there

academy of medicine, a combined membership of the Library and the Massachusetts Medical Society, and at that time it was found to be absolutely impracticable from a legal point of view

The corporate body of the Library must remain in its fellowship, and its board of trustees. To change that or to change the name of the Library would create an insurmountable legal controversy. I have been into that with legal counsel, and the trouble is that many of these bequests are left for specific purposes and that to change the name of the Library, everyone, not only the families of the donors but those who might be interested in the ultimate distribution of the property, would have something to say. Such a legal tangle would be insurmountable. The membership of the Library must remain the same so far as the corporate interest is concerned.

Dr Norman A Welch, Norfolk, asked if the legality of the recommendation had been inquired into. Dr Phippen read as follows from a letter that he had received from Mr Robert Dodge, counsel for the Library and also for the Massachusetts Medical Society:

I think that the Massachusetts Medical Society may lawfully agree to contribute \$25,000 a year toward the support and maintenance of the Boston Medical Library. Such an expenditure would seem plainly to be in the interests of the preservation of health, and therefore come within the chartered purposes of the Society.

Dr Ober pointed out there might come a time when the Library might not need the funds that the adoption of this recommendation would provide and that under such circumstances the action proposed by the recommendation could be modified or rescinded entirely.

Dr Nicholas Scarcello, Worcester, asked if it would be proper to amend the recommendation of the Executive Committee so as to provide that this grant to the Library of \$5 00 from each \$25 00 carry with it a request that the Boston Medical Library make the members of the Massachusetts Medical Society associate members of the Library. Dr Phippen said that although he could not speak with authority on the subject, he thought that something like this could be done. The President said that he would entertain Dr Scarcello's amendment.

Dr Hyman Morrison thought that such an arrangement would tend to lessen the income that now accrues to the Library from dues.

Dr Fremont-Smith, in seconding Dr Scarcello's amendment, said that unless some arrangement of this kind could be made the Council would be criticized by the men in the outlying districts. He added that he rather favored the idea of making this grant to the Library contingent on the Library entering into some such agreement.

The President said that he doubted that the Library would ignore the request contained in the amendment. He announced that the question before the Council was the adoption of the third recommendation of the Executive Committee as amended by Dr Scarcello. It was so ordered by vote of the Council. Dr Ober moved the adoption of the report as a whole as amended. This motion was seconded, and it was so ordered by vote of the Council.

Report on the December, 1946, Meeting of the House of Delegates of the American Medical Association

The report (Appendix No 10) was presented by Dr. David D Scannell, Norfolk. The President, in commenting on its excellence, said that it was informational only. The acceptance of the report was regularly moved and seconded. It was adopted by vote of the Council.

Committee to Survey Malpractice Insurance

This report, which is as follows, was submitted by the chairman, Dr Carl Bearse, Norfolk:

A meeting of the committee was held on October 2, 1946. It was voted that letters be sent to the following insurance companies underwriting most of the medical malpractice insurance in Massachusetts, secretaries of all state medical societies in the United States, and all members of the Massachusetts Medical Society, together with a questionnaire to be completed:

The letter to the insurance companies inquired as to the number of physicians insured by them in Massachusetts, the number of Massachusetts Medical Society members insured, whether they accepted graduates of unapproved medical schools, the amount of money paid out in settlement of claims during the previous ten years, the largest sum paid in the settlement of a single claim, their coverage and rates, and whether they would co-operate with a committee of the Massachusetts Medical Society by informing them of all suits or threats of suits brought against members of the Society insured by them for the interchange of opinion, provided of course that the physician insured agreed to this.

The letter sent to the secretaries of all state medical societies informed them that the Massachusetts Medical Society was making a survey of malpractice insurance in this state and that the Society would like to know how other state societies concerned themselves with this problem. The specific inquiries addressed to them were as follows: Does your society defend its members against suits of malpractice? Does your society pay any indemnity? Do you have a committee to serve as a clearing house for all suits for malpractice? What rates are charged by insurance companies in your state?

The letter and questionnaire sent to all members of the Massachusetts Medical Society are not being repeated here since they have already been mailed to every fellow. Replies are still coming in and are being tabulated for study.

This report is purely informational and is submitted as one of progress.

Dr Bearse moved the acceptance of the report. This motion was seconded, and it was so ordered by vote of the Council.

Committee on Physical Medicine

This report, which is as follows, was presented by the chairman, Dr Arthur Watkins, Middlesex South:

No new business has been brought before this committee, but the following informational report is submitted. In view of the several substandard schools for training physical therapists in this area, it is thought worth while to inform members of the Massachusetts Medical Society that there is available a printed directory of graduates of physical therapy schools approved by the American Medical Association who are members of the Massachusetts Physiotherapy Association. Physicians will be protecting their own and their patients' interests when prescribing physical therapy if technicians carrying out the orders have had training with the high medical standards required of this group. These directories can be obtained from Mrs Dorothy V Warren, Physical Therapy Department, Massachusetts General Hospital, Boston 14.

APPENDIX NO 2

REPORT OF THE EXECUTIVE COMMITTEE OF THE COUNCIL

The Executive Committee of the Council met on January 8, 1947, in Sprague Hall, 8 Fenway, Boston, Mass., at 4 00 p m. Dr Dwight O'Hara, president of the Massachusetts Medical Society, presided. This was a regular pre-Council meeting called for the purpose of processing committee reports and for such other business as might legally come before it.

The record of the last meeting as submitted by the Secretary was approved.

Committee Reports

Report of the Meeting of the House of Delegates of the American Medical Association held in Chicago on December 7, 8 and 9, 1946

This report was submitted by Dr David D Scannell. The Executive Committee commends this report for the clarity with which it outlines the proceedings of the House of Delegates, it looks on it as informational only and recommends that the Council adopt it as such.

Committee on Arrangements

The Executive Committee notes that this report is informational only and recommends its adoption by the Council.

Committee on Publications

The Executive Committee notes that this report contains two recommendations.

The first request is that the Council authorize the publication of a directory of the officers and fellows of the Massachusetts Medical Society during the year 1947 and that the sum of \$2000 be appropriated for this purpose. The Executive Committee notes that this appropriation is provided for in the budget. The Executive Committee recommends that the Council adopt this recommendation.

The second recommends that the advisability of adopting some sort of retirement plan for the full-time employees of the Society be referred to either an existing committee or a specially appointed committee to the end that if such committee thinks that action is advisable it be empowered to present such a retirement plan to the Council. The recommendation further provides that, in the event that a plan is recommended to the Council it must first have the approval of the Committee on Finance. The committee's report explains that because of the scientific character of the Society its employees may not participate in the benefits of the present Social Security Act. The Executive Committee recommends that the Council adopt this recommendation and that this subject be referred by the President to the committee which has recently studied and reported on salary adjustments for the employees of the Society.

Committee on Public Relations

This report recommends that the Council authorize the Committee on Public Relations to establish a speakers' bureau. The Executive Committee concurs in this recommendation.

The discussion on this subject before the Executive Committee brought out several facts all of which pointed to the wisdom and necessity of establishing such a bureau. The President and Secretary spoke of the many requests that they receive from time to time from lay organizations requesting speakers on medical and medicoeconomic subjects and of their inability to find those willing to accept such assignments. They both felt that in failing to do something about this in the past, the Society has neglected a valuable means of improving its public relations.

Reference was made to the fact that the American Medical Association had established a speakers' bureau as a means of making the people as a whole more aware of what organized medicine is offering in the interest of the public good. This national bureau will be in a position to train groups of doctors from the various states from the standpoint of adequately informing them not only on the subjects to be discussed but also on the methods of approach likeliest to succeed.

The Committee on Public Relations asks the privilege of organizing this movement in the Society. It would make its selection of speakers from all parts of the state. The Executive Committee also believes that by adopting this recom-

mendation the Council would give at least some direction to the office of the Director of Medical Information and Education and that this office might as one of its duties work with and under the direction of the Committee on Public Relations in setting up and supervising the bureau called for in this recommendation.

Committee on Legislation

The Executive Committee regards this report as informational only and recommends its adoption as such.

Committee on Finance

This report presents the budget for the year beginning January 1, 1947. The Executive Committee recommends the adoption of the budget as presented by the Committee on Finance.

Report of the Committee on Society Headquarters

This report takes notice of the poor state of the Society's mechanical office equipment and of its inadequacy in meeting the demands put on it. The Executive Committee points out that the moneys necessary to carry out the recommendations contained in this report are incorporated in the budget as submitted. The Executive Committee recommends the adoption of the recommendations contained in this report.

Committee on Public Health

In reviewing this report the Executive Committee gave first consideration to that part of the report submitted by the Subcommittee on School Health. The discussion indicated that this subcommittee came into being as the result of a mandate of the Council which was motivated by a letter that Dr Fitz received from a committee of school executives asking that the Massachusetts Medical Society set up a committee that would study ways and means of improving medical services in schools. The Executive Committee notes that the subcommittee's principal recommendation begins as follows: "To establish an effective liaison between representatives of the Massachusetts Medical Society and educational officials at both state and local levels." The Executive Committee is in support of this proposal.

The Executive Committee notes that the subcommittee would activate this idea by (a) having the Massachusetts Medical Society appoint an over-all committee on school medical services, and (b) having each district society appoint a local committee on school medical services, it being understood that each district would apply this principle according to the needs of the individual district.

With regard to "a," the Executive Committee recommends that the word "over-all" be deleted and that the word "advisory" be substituted. The Executive Committee is impelled to this action because it believes that the latter word more clearly describes the function of such a committee and the limitations that should govern its activities.

With regard to "b," the Executive Committee in carrying out the same idea, recommends that the word "advisory" be placed between the word "local" and the word "committee." The Executive Committee also recommends the deletion of the following language: "it being understood that each district will apply this principle according to the needs of the individual district." The Executive Committee is impelled to this action by reason of the fact that it regards these lines as redundant.

The Executive Committee notes that this report contains thirteen additional recommendations. Although it expresses its sympathy with what it conceives as the idea behind most of these recommendations, it recommends that they be referred to the advisory committee heretofore proposed by this report for further study and elucidation when and if such a committee is set up. The Executive Committee is impelled to this action because of the magnitude of the recommendations and because certain practical questions are in need of answer before the Council should commit itself.

In referring these remaining recommendations to the proposed advisory committee the Executive Committee suggests that the Council specifically direct the attention of such an advisory committee to recommendations 11 and 12, to the end that the language of these recommendations be changed so that the interpretation of physical findings

is need for such a community rehabilitation center and service in Boston, organized in accordance with the *Report of the Baruch Committee on Physical Medicine*

The President referred this resolution jointly to the Committee on Rehabilitation and the Committee on Industrial Health

At this point in the meeting, Dr Daniel B Reardon, Norfolk South, said that because he was late in entering the meeting he did not know whether or not any action had been taken by the Council regarding Dr Tighe's illness. The President replied that in opening the meeting he had acquainted the Council with the fact that Dr Tighe was ill. He added that he talked with him over the telephone that morning, that the latter's spirits seemed good and that he expected to be around again shortly. The President said that a box had been placed in the hall outside the Council room for the benefit of all those who wished to participate in sending the secretary a modest and appropriate remembrance.

The President announced that there was no further business before the Council. It was moved and seconded by vote that the Council adjourn.

The president announced the Council adjourned at 120 p m.

MICHAEL A TIGHE, *Secretary*

As touching on the necessity of increasing the dues, the Treasurer, Dr Eliot Hubbard, Jr., submitted the following

For basic comparison the income for 1946 was as follows

Annual dues	\$51,522
Nonresident dues	1,776
General Fund	5,162
Phillips Fund	250
Censors' fees	1,185
Profit (Committee on Arrangements)	5,301
Profit (Postgraduate Assembly)	835
	<hr/>
	\$66,031

Income from the *Journal* is not included as it is not a constant sum, nor certain as a future source

Taking the same income figure for 1947 and the budget estimate for 1947 of \$64,195, there would only be a clearance of \$1,836. This would not take care of the proposed salary of the Director of Medical Information and Education, to say nothing of other proposed and worthy expenditures. Therefore, some increase in dues is necessary.

In considering the increase in dues in the light of new and proposed expenses, it must be remembered that the increase applies only to annual dues, not to nonresident dues.

It has been advocated that the annual dues be increased to \$25.00 and that \$5.00 of this be allocated toward support of the Boston Medical Library. If this was done, the income and expense accounts would be as follows

<i>Income</i>	
Annual dues (200 resident fellows)	\$150,000
Other income	14,509
	<hr/>
Total	\$144,509
<i>Expenses</i>	
Budget	\$64,195
Boston Medical Library	26,000
Ultimate salary of Director of Medical Information and Education	10,000
	<hr/>
Total	\$100,195
Credit balance	\$44,314

If the dues were increased to \$20.00, the income and expense account would be as follows

<i>Income</i>	
Annual dues	\$104,000
Other Income	14,509
	<hr/>
Total	118,509
Estimated expenses	100,195
	<hr/>
Credit balance	\$18,314

This might seem adequate at the moment, but other projects are being proposed, namely, a retirement fund for the full-time personnel in the administrative office, a fund to aid and assist member physicians incapacitated through illness, injury or age, and like aid for needy widows and orphans of members. With these in mind and the annual increase in administrative expense that has occurred regularly over many years, it might not be long before the dues would have to be increased to \$25.00 from \$20.00, if the latter figure were now agreed on. If the annual dues be raised to \$25.00, I should like to make the following suggestions

That the refund to district societies be increased from \$4,000 a year to \$8,000
That the total amount of the assets of the General Fund be set at some figure agreed on by the Committee on Finance, perhaps \$250,000, and not be increased each year by reinvestment of surplus, as is up to now possible and customary for no specific purpose, and that in any given year, after running expenses have been paid and aid to the Boston Medical Library and other beneficiaries given, the balance of income over expenditures be automatically turned over to the Building Fund. This fund so augmented would assure the purchase of adequate headquarters at the proper time and would allow for a Building Fund endowment, the income from which would support the running of this establishment

Dr Walter G. Phippen, a member of the Executive Committee and president of the Boston Medical Library, made a statement as to the needs of the Library, which was in much the same vein as previously reported to the Council by the Executive Committee. He said that if the Library had an additional income of \$25,000 to \$30,000 yearly, it could become a very valuable instrument to all the physicians of the Commonwealth. He said he realized that the Library was not doing the job that it should. He explained this by saying that it did not have sufficient funds. He added that it was his feeling that the Library occupies a position toward the profession of medicine in Massachusetts exactly the same as that occupied by a public library toward the taxpayers of the community.

In response to a question, Dr Phippen said that with additional funds available with which to sort and catalogue books, which were at present piled up in many places, more space, to the extent of two or more large rooms, might be made available for the use of the Society. The discussion also brought out the fact that if funds were made available to the Library, it could send books to any member of the Massachusetts Medical Society and therefore be of service to all.

With all these considerations in mind, the Executive Committee believes the membership dues should be increased. It also believes that, out of this increase, a certain allotment should be made to the Library. It therefore recommends

That the Council set the membership dues at \$25.00 per year

That the rate become effective January 1, 1948

That of this \$25.00, \$5.00 be earmarked for the use of the Boston Medical Library

Committee Surveying Malpractice Insurance

The Executive Committee recommends that this report be accepted as one of information.

Committee on Physical Medicine

The Executive Committee recommends that this report be accepted as informational.

Committee to Study the Income Level for Blue Shield

The Executive Committee was much confused by this report. It recommends that the Council refer it back to the committee for elucidation.

Committee to Meet with General Hawley

This report is informational only, and the Executive Committee recommends its acceptance as such.

MICHAEL A. TIGHE, Secretary

APPENDIX NO 3

REPORT OF THE COMMITTEE ON PUBLICATIONS

The *New England Journal of Medicine* has operated successfully so far this year. The outlook for next year is also bright. We hope that it will not be necessary to call upon the Society for any funds for the year 1947, but the situation is so uncertain, owing to the rise in price of materials, that we ask for an appropriation of \$5,000 to be drawn on if necessary. The estimated revenue and expenses for the year 1947 are shown on the statement which has been submitted to the Treasurer and the Committee on Finance. This statement is included in the report of the Treasurer. A full report of the operation of the *Journal* will be submitted at the annual meeting of the Council in May.

It has been customary to publish a *Directory of Fellows* every two years. The last one was published in 1945. Therefore a new directory should be published in 1947. The committee believes that it is important to publish a directory in 1947 because there have been so many changes in the addresses of fellows since the publication of the last directory. We therefore request an appropriation of \$2,000 for the publication of the Directory.

For the past year, the Committee on Publications has seriously considered the adoption of some sort of retirement plan for the full-time employees of the *Journal*. Since the employees of a non-profit educational organization are not entitled to the benefits of the Social Security Act, it seems

shall remain in the hands of the physician and not be shared with the school nurse

The Executive Committee recommends that the Council approve the recommendation providing that the Council authorize the President to appoint a subcommittee of three to act as liaison between the Society and the Massachusetts State Department of Mental Health

The Executive Committee approves the first part of the report dealing with Dr. Getting's program but notes that the last part concerns public-health personnel. If this were approved by the Council, it would commit the Society in a manner in which it should not be committed. It therefore recommends that the Council take no action on these lines on the ground that action on this subject is beyond the scope of the Society.

The remainder of the report of the Committee on Public Health is informational, and the Executive Committee recommends its adoption as such.

Committee on Postwar Planning

The Executive Committee notes that the first part of this report is informational. It recommends adoption of this part of the report.

The Executive Committee notes several recommendations. This Committee is in accord with all these recommendations except that which would authorize the creation of a special committee of five members to be appointed by the President, subject to confirmation by the Council, to consider the advisability of setting up a board of trustees within the structure of the Massachusetts Medical Society.

The Executive Committee recommends that the Council disapprove of this recommendation. In the discussion attending this subject, it came out that the Executive Committee, consisting of one representative from each district in the Commonwealth, had been performing what might be regarded as the functions of a board of trustees, but that there was a feeling in the Committee on Postwar Planning that there was at times a lack of over-all policy due to the size of the Executive Committee and the shortness of time (three years) in which any single member might hold continuous office. On the other hand, it was emphasized in this discussion that there never had been any difficulty in getting the Executive Committee together even in emergency session and that a board of trustees might result in too centralized a government, which might affect unfavorably the democratic character of the Society and alienate the interests of the ordinary member. The wisdom of setting up a board of trustees, which in the ordinary course of events might be expected to take over the functions now being satisfactorily performed by the Executive Committee, was seriously questioned. It was pointed out that the recommendations did not actually propose that such a board of trustees be set up, but only that a committee be authorized to study this subject. It was also pointed out that a board of trustees might be needed to give direction to the efforts of the Director of Medical Information and Education. There were district societies that reported their councilors as unanimously opposed to the proposal.

It was noted that the final recommendation by the Committee on Postwar Planning was that it be discharged. The Executive Committee in recommending that the Council adopt this recommendation also recommended that this discharge carry with it the expression of the Council's gratitude for a job well done and that this expression of gratitude be in a special manner directed toward the chairman, Dr. Root, who had given so generously of his time and talent over a period of years.

Committee Appointed to Nominate a Director of Medical Information and Education

The Executive Committee recommends the adoption of the recommendations contained in this report.

Committee on Postgraduate Assembly

The Executive Committee notes that this report contains two recommendations that a committee be appointed to arrange an assembly in 1947 and that the Council approve of the setting up of an independent organization to be known as the New England Postgraduate Assembly.

The thinking in the Executive Committee with regard to the second recommendation was that if the postgraduate

assemblies were to be operated by all the New England state medical societies, it was desirable that they be given sponsorship and direction by an organization that was a ready officially representative of these state societies. It was pointed out that the Council of the New England State Medical Societies was so representative and that at a meeting of the Council, which was scheduled for January 1, 1947, the taking over of this activity was to be considered by this council. It was explained that this council was made up of three representatives from each of the New England state medical societies and that it had its support from an equal assessment on each society and that that sum up in this time was one hundred dollars yearly. It was also pointed out that the manner in which the last assembly was operated demonstrated that this activity might be run at a profit.

The Executive Committee took no action on these two recommendations. The Secretary was instructed to ascertain the desires of the Council of the New England State Medical Societies in this matter and to make known in the report to the Council of the Massachusetts Medical Society what those desires were. The Secretary, as a representative of the Massachusetts Medical Society, was present at the meeting of the Council of the New England State Medical Societies, which was held in Boston on January 15, 1947. The following motion was adopted at that meeting:

That the Council of the New England State Medical Societies postpone action for the present relative to sponsoring the New England Postgraduate Assembly until it can obtain the point of view of the individual state medical societies regarding their participation as co-sponsors.

It was pointed out that the action called for by this meeting could not be consummated by many of the state societies before June, 1947, and that even if it was favorable to the proposition, this would be too late to begin to plan for an assembly to be held in the fall of 1947.

It seemed to be the feeling generally that an assembly should be conducted in 1947 on much the same basis as it has been in the past and that before it was time to plan for the 1948 assembly, the Council of the New England State Medical Societies would know whether or not this was an activity which it would take over. (The Secretary would like to say that all this indicates that the Council might see fit to approve the first recommendation of the Committee on Postgraduate Assembly and lay the second one on the table. It must be emphasized that the above is a suggestion which comes from the Secretary alone, the Executive Committee as a whole having had no opportunity to review the information here recorded.)

Committee to Study an Increase in Assessment of Dues

This report reviews the present activities of the Society and such other activities as have from time to time been discussed as properly belonging in its sphere. The discussion concerns itself with the costs involved and concludes that the dues will have to be raised if the program outlined is to be realized. It notes that at one time an increase of \$10.00 was discussed in the Executive Committee, which would make the dues \$20.00. While noting the needs of the Boston Medical Library and the necessity of helping to meet those needs, the report makes no specific recommendation as to the amount that the Society should contribute. The report concludes as follows:

After reviewing the suggestions for future plans for the Society, it may be necessary to raise the dues to \$20.00. With such a program as outlined above it will probably be necessary to make further study in order to present a comprehensive plan covering all contingencies for the present and the future. The dues should be raised sufficiently so that it will not be necessary to raise them again.

The following quotation from the report of the Committee on Finance was then read into the record:

In the future, the salary of the Director of Medical Information and Education will add a sum to our annual budget which can hardly be expected to be covered by our present sources of income. The appointment of such a director will call for an increase in dues or for some other method of raising the amount of his salary and the expenses of his office.

only reasonable that some provision should be made for retirement allowances, when these people reach a certain age. Indeed, many commercial companies have, in recent years, adopted retirement plans that supplement the Social Security benefits.

At the last meeting of the committee, held on December 4, it was suggested that, since the Society has an appreciable number of full time employees, it likewise might consider a retirement plan, and that if such a plan were adopted, it would be well for the *Journal* to follow an identical plan.

The committee therefore makes the following recommendations to the Council:

That the advisability of adopting some sort of retirement plan for the full-time employees of the Society be referred to a committee of the Society, either an existing committee or a specially appointed committee according to the desires of the President, and that, if the adoption of such a scheme seems desirable, a specific retirement plan be presented to the Council, subject to approval by the Committee on Finance, if the matter was not referred to said committee.

Dr William Dock, Director of Medicine, Long Island College of Medicine, Brooklyn, New York, has been secured to deliver the Shattuck Lecture in 1947.

APPENDIX NO 4

REPORT OF THE COMMITTEE ON FINANCE

The figures which make up the bulk of the report of the Committee on Finance are not to be regarded as a complete accounting of the finances of the Society. They represent a reasonably accurate estimate of expenditures based on the amounts paid out by the Treasurer during the first ten months of the current year plus an additional 20 per cent intended to cover the probable expenses for the remaining two months. This estimate, together with requests received from the various committee chairmen, serves as the basis of the budget which the by-laws of the Society require us to recommend to the Council for the proximate fiscal year. For purposes of comparison, similar items of expenditure for the current year are recorded, together with the estimates which made up the 1946 budget. We have appended similar estimates of income received by the Society during 1946.

A comparison of expenditures with income shows that we are operating well within our resources. Expenses were less than the amount anticipated in the 1946 budget, and income was greater, for example, income from dues amounted to approximately \$52,000 instead of the expected \$45,000. In the future, the salary of the Director of Information and Education will add a sum to our annual budget which can hardly be expected to be covered by our present sources of income. The appointment of such a director will call for an increase in dues or some other method of raising the amount of his salary and the expenses of his office.

Most of the items in the budget are self-explanatory. Unusually large items are explained in the footnotes. The amounts requested by the committee chairmen have in most instances been reduced to a slight degree. This reduction is based on the fact that items referring to clerical services were subtracted in accordance with the expressed offer of the secretary, Dr Tighe, to provide facilities at the Society headquarters for the performance of all the clerical work of the various committees so far as possible. It is hoped that this will relieve the committee chairmen of much clerical work. The plan is intended to assist them, not of course to interfere with their present methods except in so far as it will work for greater convenience and efficiency. The budget for headquarters committee expense and general administrative expense reflects this plan, as supplies and all salaries for clerical assistants are included in these items.

APPENDIX NO 9

REPORT OF THE COMMITTEE TO STUDY INCREASE IN ASSESSMENT OF DUES

The committee held a formal meeting on Sunday, December 8, 1946, at 2.30 p.m. There were present Dr. Edwin Gardner, Marion, Dr. John W. McKeon, Worcester, Dr. Kenneth L. MacLachlan, Melrose, and Dr. Frank R. Ober, Boston. Dr. N. Newall Copeland, Pittsfield, was absent.

The members were written to on November 7, 1946, and advance information was sent each one relative to annual dues of all the New England state medical societies and the Massachusetts Dental Society, as well as the Treasurer's report at the last annual meeting. No reply was received from the absent member, although two letters were written to him.

In discussing the matter of increasing the annual assessment, your committee considered

- 1 The present cost of running the Society
- 2 The raising of salaries of the central office personnel
- 3 The raising of the salaries of the Treasurer, Executive Secretary, Secretary and Miss Gaston
- 4 The salary and expenses of the Director of Medical Information and Education
- 5 The possibility that the office of the Secretary of the Society be made full time and receiving adequate compensation therefor
- 6 The relation of the Boston Medical Library to the Massachusetts Medical Society
- 7 The advisability of some form of financial support to widows and orphans of physicians
- 8 The advisability of financial aid to certain physicians incapacitated by chronic illness or some other cause and unable to support themselves and their families
- 9 A retirement fund for the full-time workers of the Society
- 10 The fact that the present headquarters are totally inadequate for the transaction of the Society affairs. There is only one room for committee meetings
- 11 A long-range plan to establish a headquarters which will house the Society

These paragraphs are discussed in some detail as follows

1 Given a membership of 6000 and dues of \$10.00 per year, plus excellent general economy, the Society can manage but this does not allow for critical expansion which is needed right now. In bad times, there would not be enough without jeopardizing the general fund.

2 Salaries of the clerical force have been raised this year and the clerical force has been increased. The present cost per year is \$5,876, an increase of \$512.

3 The yearly compensation of the Treasurer is now \$2,500, of the Secretary, \$4,000, of the Executive Secretary, \$4,800, and of Miss Gaston, \$2,184—a total of \$13,484. The total increase of salaries is \$2,996.

4 It has been recommended by the Committee of Seven that a Director of Medical Information and Education be secured at a salary of \$7,500 for the first year, which is to be increased by \$500 each year until a maximum of \$10,000 is reached. In addition to this sum, there must be added an indefinite sum for necessary expenses. This position is to start July 1, 1947.

5 Your committee is of the opinion that the time has arrived when it is to the best interests of the Society to consider seriously the advisability of having a full-time secretary on a more permanent basis than exists now. An adequate salary must be provided to meet this situation. The duties of the Secretary's office are increasing steadily and some time in the not-too-distant future it will be a continuous performance. The office of a full-time secretary would be open all the time in order that physicians may be able to seek advice of the secretary any weekday. This would in itself make the Society more valuable to its members.

6 The relation of the Boston Medical Library to the Massachusetts Medical Society was considered at some length. The Boston Medical Library is in need of financial assistance. It is believed by your committee that the Library is a real asset to the Massachusetts Medical Society. If through lack of sufficient income, it became necessary for the Library to close its doors, the whole medical profession of the Commonwealth would suffer.

The trustees of the Library have tried to get needed help from many sources, but without success. This is the third largest and one of the oldest medical libraries in the United States. Its membership is small—nine hundred and thirty-two. Its dues are \$15.00 per year. It is used by a great many who pay nothing, and many of these will not become members because they get service free. This situation is unfair to the Library and those loyal members who do pay. The Library can be made useful to every member of the Society.

The *New England Journal of Medicine*, which is owned and run by the Massachusetts Medical Society, is a constant user of the facilities of the Library. This is an important factor in the publishing of the *Journal* because bibliographies of articles must be checked. The fact that the Library is in the same building as the *Journal* makes this easy and saves a great deal of expense and time. This would not be true if there were no Library available.

This is a distinct asset to the Society and is one of the many reasons why the *Journal* is having so much success and a constantly increasing distribution. It would seem, therefore, that the Library is a real asset to the Massachusetts Medical Society for which there does not seem to be an adequate return. It is recommended that the Society subsidize or otherwise help the Boston Medical Library so that this valuable institution will not go under.

7 The committee recommends that some form of financial support be made to needy widows and orphans of physicians.

8 It further recommends that a fund be set up to aid and assist those physicians who through no fault of their own find themselves incapacitated through illness, injury, or age, and are not able to support their families. The Massachusetts Benevolent Society has an income of \$5,000 a year and is at present helping seventeen people who fall into this category. This society would probably be willing to integrate their fund with any proposed plan of the Massachusetts Medical Society.

9 There should be also a retirement fund for the full-time members of the central administrative office of the Society.

10 The present office space is totally inadequate for the proper conduct of the business of the Society. There is only one room in the building available for committee meetings, therefore, many meetings are held outside the building and at some extra cost. It would be to the advantage of all concerned could they be held at the headquarters.

The Headquarters Committee voted that the Society secure more room from the Library by helping the Library to construct stacks for books and so forth that are stored on the floors and against the walls of the building, thus taking up space that would be freed could the Library afford to construct stacks and secure more help in placing and cataloging these books. This would give us more urgently needed rooms for meetings and business purposes and would be a distinct help for the present.

11 Your committee is in sympathy with the proposed plan of the Headquarters Committee of the Society. This proposed plan is a long-range one and depends largely on securing a site near the Library and the *Journal*. The Massachusetts Medical Society should have a home adequate to take care of all the facilities of the Society for at least fifty years. This means sufficient office and committee rooms, a larger banquet hall for the Council, a kitchen for the benefit of the working officers and clerical help at the headquarters. The possibility of an auditorium large enough to hold the annual meeting might well be considered. Smaller meeting rooms in the same building would be necessary.

With this long-range plan in mind, an increase in the annual assessment might be a good thing to do now, so that a portion of such increase could be set aside and allowed to accumulate as a sinking fund to be used in any new additions or construction of adequate facilities for the future.

The present dues are \$10.00 per annum, which includes the subscription to the *Journal* and the "turnback" to the dis-

APPENDIX NO 8

REPORT OF THE COMMITTEE APPOINTED TO NOMINATE A
DIRECTOR OF MEDICAL INFORMATION AND EDUCATION

Because of elapsed time since the Council assigned this study to the committee, it seems desirable to review the whole situation

The growth of the Society and expansion of activities have been such that it became increasingly apparent to several committees and individual fellows that the time had come to create a new position for the handling of public relations, legislation and other matters which would inevitably arise in future Society activities. Toward this end, a special committee, the Committee on Public Information, studied the situation last year, conferring with Society committees, public relations experts, health educators, newspaper and radio men and so forth and then, together with the Postwar Planning, Legislative and Public Relations committees, placed the matter before the Council. On October 3, 1945, the following resolution was adopted by the Council

WHEREAS, We consider that the Massachusetts Medical Society is under obligation to make its educational facilities of increasing usefulness to fellows, to all licensed physicians in Massachusetts and to the public, therefore, be it

RESOLVED, That the Massachusetts Medical Society hereby creates a new position, its holder to be known as the Director of Medical Information and Education, charged with the duty of promoting in an ethical manner the educational usefulness of the Society to its fellows and to the public and also charged with the performance of such other duties as the Society or the Council may require, and be it further

RESOLVED, That such a Director of Medical Information and Education shall be appointed by the Council on proposal of a Committee of Seven named by the President

The President appointed this committee as follows: Elmer S. Bagnall, David Cheever, Roger I. Lee, Charles E. Mongan, Frank R. Ober, Walter G. Phippen and George L. Schadt, with the President and President-Elect members *ex officio*.

Since retiring from the presidency of the Society in May, 1946, Dr. Reginald Fitz has been a party to the committee's discussions, as has President-Elect Edward P. Bagg.

The first meeting of this committee was held on October 24, 1945. Dr. Fitz was appointed as the first chairman and Dr. Bagnall was elected secretary.

Since that time, numerous meetings have been held. The committee felt that the selection of the right man required a definition of his duties far more precise than is given in the vote of the Council, to the end that his qualifications and attainments should be adapted to those duties. Therefore, they first studied the broader aspects of this field. Letters were sent to all state societies. Replies were received from more than half, some of which sent voluminous evidence of activities. Many issues and problems were brought to light. Letters to Dr. Creighton Barker, who holds a similar position in the Connecticut State Medical Society; Dr. Olin West, secretary of the American Medical Association; Thomas A. Hendricks, secretary, and Dr. Joseph S. Lawrence, director of the Council on Medical Service and Public Relations of the American Medical Association brought forth advice and recommendations. The presidents of our district societies were contacted by letter for assistance in locating a man but only one or two suggestions were forthcoming.

In May, 1946, the committee made a report to the Council which said, in part

The committee feels that much of the work of the new director must at first be of an exploratory and tentative character and that its final emphasis and value cannot be predicted. Much will depend on the particular talents which he may bring to his office. They believe that ideally the incumbent should be a physician, a member of the Society, experienced in practice, and in early middle life, so that before him may stretch a long career of usefulness, which will steadily increase with his experience. Such a man must, of course, be on a full-time basis, and receive a salary sufficient to enable him to relinquish the income from a successful practice. His appointment should be terminated on his reaching a prescribed age, as in the case of academic or teaching appointments.

The committee has failed thus far to discover a suitable candidate with all these qualifications. They agree that the selection of the candidate is a matter of paramount importance and have preferred to proceed with caution rather than run the risk through haste of committing a grave error. This report, therefore, is one of progress and contains no recommendation.

Although several men had been suggested as possibilities for the position of Director of Medical Information and Education, none were considered by the committee as having the proper qualifications until the name of Dr. John F. Conlin was brought to the attention of the committee by letters from Dr. Elliott Cutler, Dr. John Fallon and Dr. Sidney Farber.

Investigation brought out these essential facts about Dr. Conlin:

John Francis Conlin was born in Schenectady, New York, in 1908. His father was a research metallurgist with the General Electric Company. He was educated in the public schools of Schenectady and attended the Holy Cross Preparatory School from 1923 to 1926.

From 1926 to 1932 he was under monastic orders in the Passionist Monasteries at Dunkirk, Springfield, Scranton, Baltimore and Boston. In 1932, he decided that he was more fitted for the study of medicine than for a career in the Church.

He, therefore, returned to the secular life, attended Boston College from 1932 to 1934, receiving the degree of Bachelor of Science, and attended Tufts College Medical School from 1934 to 1938. He was president of his class throughout the four years of medical school and was chairman of the Student Activity Board during his senior year. On graduation, he received the "Alumni Award" of the medical school.

He served an internship in 1939 and 1940 at St. Elizabeth's Hospital in Brighton and served as resident at the John Adams Hospital in Chelsea from 1940 to 1941. He entered active duty with the Army in 1942, he went overseas in 1944, he returned a lieutenant colonel in 1945 and was discharged with a full colonel's rating in 1946.

During the 1945-1946 season, he came to the attention of several committees in the Society because of his assignment to fight the Antivivisection Bill before the Legislature last year. During part of this period he worked with the Veterans Administration and in the fall of 1946 he entered the Harvard School of Public Health.

He joined the Massachusetts Medical Society in 1941 and he was elected a Councilor in 1946. He was appointed to the Committee on Arrangements last spring in recognition of the splendid job he had been doing on the antivivisection legislation.

At the meeting of the committee on September 20, it was decided to interview Dr. Conlin either individually or in groups.

A meeting was held on November 14. At that time Dr. Conlin had been interviewed by all members and had made a most favorable impression on the majority of the committee. Discussion ensued as to his qualifications, his duties, salary and so forth. It was voted that the President and President-Elect, as a subcommittee, interview Dr. Conlin regarding salary, not to exceed \$10,000, and that if satisfactory financial arrangements developed, he be nominated for the position of Director of Medical Information and Education.

From the report of this subcommittee, the Committee of Seven makes the following recommendation to the Council:

The Committee of Seven proposes that Dr. John Francis Conlin be appointed by the Council as Director of Medical Information and Education.

Dr. Conlin will be available at the close of the school year, and it is recommended that he begin as of July 1, 1947, at the salary of \$7,500 per annum, plus ordinary traveling expenses, and with appropriate vacation periods. If his services are satisfactory and if he is satisfied with the work as it develops, he is to receive an increase of \$500 on January 1, 1948, and on each January 1 thereafter until the maximum salary of \$10,000 would be reached on January 1, 1952. If there should be gross inflation in our national economy, adjustments should be expected. There should also be an understanding concerning a mutual termination of the agreement.

47 Just how much of the Rich Report will be printed in the minutes is problematical, but the findings and recommendations of the Interim Committee will probably be noted in full

Announcement of plans for the Centennial Meeting at Atlantic City in June were made by the proper committee, most extensive program has been lined up along all lines, and even now all the details of speakers and subjects have been worked out. All give promise of an ideal centennial meeting. Dr Lull, as secretary and general manager, is working out satisfactorily, having at all times the invaluable help of his predecessor, Dr Olin West

Admiral Joel T. Boone, head of the Investigating Board of the United Mineworkers' problem appeared by invitation before the House of Delegates. His discussion of this rather incomplete report was given in executive session, the report is not yet finished, and he could not definitely state all the findings, but he did state enough to give us con-

siderable concern about the health conditions existing in many of these soft-coal mining areas. Admiral Boone is a man of keen and analytical mind and eminently humane and fair. He stated that there is a great field here for the American Medical Association in health education, public relations and needed co-operation with the physicians working in those fields. His talk took well over an hour. At the end, he himself gave what he thought was a fair release of those portions of his remarks to which he felt the public was entitled

Obviously, I have omitted many items that deserve comment in the transactions on Monday, Tuesday and Wednesday, but you must refer for these to the printed minutes. All in all it was a most profitable meeting and demonstrated the wisdom of having interim meetings between the annual meetings of the House of Delegates

CASE 33161

PRESENTATION OF CASE

A twenty-year-old American tool worker entered the hospital because of swelling of the right lower leg.

The patient had had no trouble until six weeks before entry, when he noted the gradual onset of painless swelling about the right ankle. There had been no preceding injury. He stopped work for three days, and the swelling decreased, only to recur when he returned to work. Five weeks before entry the swelling became localized in the posterior and lateral portions of the lower leg, just above the ankle, and he began to have an aching pain in this region. The pain was brought on by dorsiflexion of the foot, which "stretched the skin" over the swelling; it never troubled him at night. The patient consulted a physician, who found that he had a temperature of 100°F and started him on oral penicillin therapy. The patient failed to improve and consulted another physician, who took x-ray films of the leg and told him that he had a "tumor." He had lost 13 pounds during the half year before entry.

Physical examination showed a hard irregular mass, about 15 cm in diameter, surrounding the lower third of the right fibula and presenting mainly on the posterior and lateral side of the leg. It did not involve the joint and stopped just above the lateral malleolus. An infiltrating projection ap-

peared to run beneath the Achilles tendon and jutted out on the posteromedial aspect of the leg as a nodule about 7 by 2 cm in size. Dorsiflexion of the foot could not be carried out beyond an angle of 85°, whereas the left foot flexed to 70°. The other motions of the ankle, including plantar flexion, were normal. The skin over the lateral aspect of the leg was slightly dusky in color. There were soft to firm lymph nodes measuring up to 2 cm in diameter in the axillas, left inguinal region and both saphenous regions. Otherwise, the examination was not remarkable.

The temperature was 98.6°F, the pulse 104, and the respirations 20. The blood pressure was 154 systolic, 94 diastolic.

Examination of the blood revealed a hemoglobin of 16 gm and a white-cell count of 13,400, with 79 per cent neutrophils. X-ray examination showed a soft-tissue mass about the right lower fibula into which irregular spicules of bone extended from the fibula. The margins of the bone were slightly irregular and indefinite, and there was a suggestion of periosteal-layer formation. The medullary structure was disorganized, and the cortex had a somewhat moth-eaten appearance. Examination of the chest was negative.

Operation was performed on the second hospital day.

DIFFERENTIAL DIAGNOSIS

DR. ERNEST M. DALAND: This patient's physician immediately thought of osteomyelitis and, with the slight degree of temperature, was justified in trying penicillin. The loss of weight apparently antedated the first symptoms in the leg. I should like to ask whether there was any determination of the calcium, phosphorus and phosphatase.

DR. TRACY B. MALLORY: The calcium was 10 mg per 100 cc. It was impossible to determine the phosphorus and phosphatase because of hemolysis.

DR. DALAND: May we see the x-ray films?

DR. TOUFIC KALIL: The soft-tissue mass is projected mainly posteriorly and involves the lower half of the leg down to the articular surface of the

strict societies. A questionnaire on dues was sent to the New England state medical societies, as it was thought that information on this subject would be valuable to us all. The following information was obtained:

New Hampshire Medical Society	\$10
Maine Medical Association	35
Rhode Island Medical Society	40 (\$25 first year of practice)
Connecticut State Medical Society	20
Vermont State Medical Society	35 (of this, \$5 is earmarked for needy physicians)

In summary, it appears that an increase in dues will be needed for the following reasons:

- 1 To meet our old obligations and our new obligations
- 2 To provide a fund or funds for retirement purposes as recommended
- 3 To help the Boston Medical Library and increase the room of the present headquarters
- 4 To develop a building fund
- 5 To provide a sinking fund in order to take care of needy physicians

The committee has recommended that the annual dues be raised to \$20.00. After reviewing the suggestion for future plans for the Society, it may be necessary to raise the dues to \$25.00. With such a program as above outlined, it will probably be necessary to make further study in order to present a comprehensive plan covering all contingencies for the present and the future. The dues should be raised sufficiently so that it will not be necessary to raise them again.

APPENDIX NO 10

REPORT ON THE TRANSACTIONS OF THE HOUSE OF DELEGATES OF THE AMERICAN MEDICAL ASSOCIATION

The following is a report of the supplementary meeting of the House of Delegates of the American Medical Association at Chicago December 7, 8 and 9. This is the first such meeting ever held not of an emergency character. Its purpose is to lighten the amount of work to be done at the annual meeting.

There was a full attendance of delegates. An interesting international note was the dropping of the representation from the Philippine Islands. These islands now constitute an independent state. At this meeting there were no addresses by the various officers, and the House proceeded at once to the matters at hand (and there were many). It was stated that the membership had increased by 3374, the total now being 129,145. Reference committees were immediately appointed by the Speaker, and as usual their work was long and exacting in most cases.

On the morning of the first day, there were given to each member copies of the so-called "Rich Report" and of the report of the Interim Committee, this committee having been appointed to analyze and make recommendations as to acceptance or rejection of many recommendations in the Rich Report. It might be of interest to know something of this whole affair.

Early in 1946, the trustees of the American Medical Association employed the Rich Associates (investigators of non-profit organizations only) to make a survey of the entire organization of the American Medical Association, with recommendations for its greater usefulness, especially along the lines of public relations. About five months were spent on this survey. It was briefly alluded to by Dr. Sensenich, president of the Board of Trustees, on the last afternoon of the annual meeting of the House of Delegates in San Francisco. He stated that the report had just lately been received, and that the House of Delegates was merely being informed briefly as to what in general it contained. This was not too satisfactory an arrangement or disclosure, and left the members in a state of critical curiosity as to just what this Rich Report contained. One may say that this statement by Dr. Sensenich was not too well timed. To offset this, the Speaker of the House later made the Committee on Executive Sessions, which had completed its work

in San Francisco, an interim committee. This committee consisted of Bates, of Pennsylvania, Carey of Texas (who never came to any of the meetings), McGlendon, of California, Lewis, of New Jersey, Hein, of Ohio, Bunce, of Georgia, and Scannell, of Massachusetts. This committee met with the trustees at Chicago in September, 1946, again met as a committee alone on December 7 in Chicago, and with the Board of Trustees on Sunday, December 8. The committee's report was then prepared and delivered to the House of Delegates on Monday morning. It was felt that this report of ours might be the high spot of the transactions of the House of Delegates and that is just what it proved to be. The House of Delegates went into Executive Session on Tuesday morning and discussed paragraph by paragraph both the Rich Report and the report of the Interim Committee. This consumed a good portion of Tuesday. We had felt that the portion of our report having to do with relations of the National Physicians Committee and the American Medical Association might prove most controversial, and that actually was the case. We recommended that this relation be studied further, and this was agreed on. The same committee, after giving the matter continued study, is to report to the House of Delegates in Atlantic City in June, 1947. Incidentally, the Rich Associates have been hired as continuing counsel to do the work suggested in their report (except as modified by the House of Delegates) for one year. Many of their recommendations were excellent, others were not so acceptable. The latter were rejected. Matters pertaining to public relations and publicity emanating from the Rich Associates are to be cleared through the office of the General Manager. The recommendations of the Committee were well received and practically universally accepted, and did much, we feel sure, to facilitate progress and to evaluate the report and its recommendations. It would take much too long to enumerate all the recommendations in this report, but the keynote of them all is to separate distinctly the functions of scientific interpretation, medical economics, socialized medicine, and the direction of public relations. They may be summarized as follows:

Vitalization of Hygeia for the reading public

Bureau of Medical Economics. In this connection, there has been appointed a Mr. Dickinson as Director of Economic Research (an admirable selection).

Public Relations. More positive type of program required, more publicity for the reading public, always, however, to be cleared through the office of the General Manager.

Health Education. An instrument of great potential importance in public relations, not yet exploited to the full, with radio, various publications, releases and so forth. This whole subject to be greatly expanded with closer liaison between state and county societies and volunteer service plans.

Council of Medical Service. Expansion of these activities with conferences on invitation from constituents or component societies at local levels.

News Letter. To be further improved and given wider dissemination.

Council of Industrial Health. More attention to be paid to industrial and consumer groups, in view of recent developments in connection with the United Mineworkers' Health Fund and similar labor, management and consumer groups.

Radio. Employment of junior radio specialist, backed by highly experienced professional counsel, if, after study, it is justified by need and cost (an expensive item).

Speakers' Bureau. This should be utilized to its fullest capacity and should be implemented by conferences with state organizations.

Prepayment Medical Care. At the present time, there are five million members enrolled and all the states but two have plans in operation.

The Women's Auxiliary. The recommendation that this be developed in states where it is not now in operation.

It must not be thought that this consideration of the Rich Report was the only subject on the agenda, but to state them all would be unprofitable. The minutes of this supplementary meeting will not be printed in the *Journal of the American Medical Association* until sometime in January,

47 Just how much of the Rich Report will be printed in the minutes is problematical, but the findings and recommendations of the Interim Committee will probably be printed in full.

Announcement of plans for the Centennial Meeting at Atlantic City in June were made by the proper committee, the most extensive program has been lined up along all lines, and even now all the details of speakers and subjects have been worked out. All give promise of an ideal centennial meeting. Dr Lull, as secretary and general manager, is working out satisfactorily, having at all times the invaluable help of his predecessor, Dr Olin West.

Admiral Joel T. Boone, head of the Investigating Board of the United Mineworkers' problem appeared by invitation before the House of Delegates. His discussion of this rather incomplete report was given in executive session, the report is not yet finished, and he could not definitely state the findings, but he did state enough to give us con-

siderable concern about the health conditions existing in many of these soft-coal mining areas. Admiral Boone is a man of keen and analytical mind and eminently humane and fair. He stated that there is a great field here for the American Medical Association in health education, public relations and needed co-operation with the physicians working in those fields. His talk took well over an hour. At the end he himself gave what he thought was a fair release of those portions of his remarks to which he felt the public was entitled.

Obviously, I have omitted many items that deserve comment in the transactions on Monday, Tuesday and Wednesday, but you must refer for these to the printed minutes. All in all it was a most profitable meeting and demonstrated the wisdom of having interim meetings between the annual meetings of the House of Delegates.

CASE 33161

PRESENTATION OF CASE

A twenty-year-old American tool worker entered the hospital because of swelling of the right lower leg.

The patient had had no trouble until six weeks before entry, when he noted the gradual onset of painless swelling about the right ankle. There had been no preceding injury. He stopped work for three days, and the swelling decreased, only to recur when he returned to work. Five weeks before entry the swelling became localized in the posterior and lateral portions of the lower leg, just above the ankle, and he began to have an aching pain in this region. The pain was brought on by dorsiflexion of the foot, which "stretched the skin" over the swelling; it never troubled him at night. The patient consulted a physician, who found that he had a temperature of 100°F and started him on oral penicillin therapy. The patient failed to improve and consulted another physician, who took x-ray films of the leg and told him that he had a "tumor." He had lost 13 pounds during the half year before entry.

Physical examination showed a hard irregular mass, about 15 cm in diameter, surrounding the lower third of the right fibula and presenting mainly on the posterior and lateral side of the leg. It did not involve the joint and stopped just above the lateral malleolus. An infiltrating projection ap-

peared to run beneath the Achilles tendon and jutted out on the posteromedial aspect of the leg as a nodule about 7 by 2 cm in size. Dorsiflexion of the foot could not be carried out beyond an angle of 85°, whereas the left foot flexed to 70°. The other motions of the ankle, including plantar flexion, were normal. The skin over the lateral aspect of the leg was slightly dusky in color. There were soft to firm lymph nodes measuring up to 2 cm in diameter in the axillas, left inguinal region and both saphenous regions. Otherwise, the examination was not remarkable.

The temperature was 98.6°F, the pulse 104, and the respirations 20. The blood pressure was 154 systolic, 94 diastolic.

Examination of the blood revealed a hemoglobin of 16 gm and a white-cell count of 13,400, with 79 per cent neutrophils. X-ray examination showed a soft-tissue mass about the right lower fibula into which irregular spicules of bone extended from the fibula. The margins of the bone were slightly irregular and indefinite, and there was a suggestion of periosteal-layer formation. The medullary structure was disorganized and the cortex had a somewhat moth-eaten appearance. Examination of the chest was negative.

Operation was performed on the second hospital day.

DIFFERENTIAL DIAGNOSIS

DR ERNEST M. DALAND: This patient's physician immediately thought of osteomyelitis and, with the slight degree of temperature, was justified in trying penicillin. The loss of weight apparently antedated the first symptoms in the leg. I should like to ask whether there was any determination of the calcium, phosphorus and phosphatase.

DR TRACY B. MALLORY: The calcium was 10 mg per 100 cc. It was impossible to determine the phosphorus and phosphatase because of hemolysis.

DR DALAND: May we see the x-ray films?

DR TOUFIC KALIL: The soft-tissue mass is projected mainly posteriorly and involves the lower half of the leg down to the articular surface of the

fibula The lower two thirds of the fibula shows a destructive process involving both the cortex and the medullary structure The periosteum of the lower end of the fibula is raised and has formed new bone For most of its length, the tumor mass is entered by narrow, irregular, calcified spicules

osteomyelitis was made, after the arm had been amputated I consider it important in doing a frozen section that the surgeon assume the responsibility of the diagnosis, share the responsibility of the gross diagnosis with the pathologist and bear with him in his difficulty in making a diagnosis on

FIGURE 1 Photograph of Fibula and Tibia

At the right may be seen the sectioned tumor in the lower end of the fibula, as well as the sectioned normal tibia

projected at right angles from the shaft of the fibula The tibia is not involved

DR DALAND Are we dealing with infection or with tumor? If a tumor, was it malignant or benign? I do not believe that we have enough evidence to make a diagnosis of infection The x-ray films do not suggest osteomyelitis to me The temperature and the systemic findings are not severe enough for osteomyelitis I do not know how long the penicillin was continued or how complete the therapy was We are told that the patient did not receive any benefit from it, but we should not expect him to unless the drug was given in large amounts for a considerable time

I think that this case comes down to a diagnosis of Ewing tumor or osteogenic sarcoma — the raised periosteum is always suggestive of the former, and the destruction of the cortex can be due to either one or the other The soft-tissue mass is not easily seen in the film but does not seem nearly so impressive as one would expect with a mass 15 cm in diameter There is not so much new-bone formation in the mass as I should expect in an osteogenic sarcoma I am inclined to think that this was a Ewing tumor

This is a difficult diagnosis to make on frozen section, as has been said before If I were going to treat this patient I should do a biopsy and wait until the pathologist had got his final sections through before going ahead with amputation I recall a case like this in a man on whom a diagnosis of Ewing tumor was made preoperatively by the radiologist, by the surgeon who operated and by the pathologist on frozen section A few days later the decision was changed, and the diagnosis of chronic

frozen section I prefer to wait and do a radical operation after all the opinions are in

I believe that the diagnosis in this case is a Ewing sarcoma

DR MALLORY Dr Taylor, you saw this patient have you any comments?

DR GRANTLEY W TAYLOR I went through the same process of reasoning as Dr Daland did We find constantly in bone tumors that we cannot make a diagnosis by palpation I sympathize therefore when the pathologist has to make it histologically, but it seemed obvious that the patient in the case under discussion had a malignant tumor of the leg, and the differential diagnosis rested between an osteogenic sarcoma and a Ewing tumor We included both in our preoperative diagnosis believing that the pathologist could make the decision on frozen section or could at least decide that it must be one or the other and rule out benign conditions I am interested in Dr Daland's anecdote in which amputation was carried out for osteomyelitis, because I had supposed that an adequate frozen section would reveal whether one was dealing with a neoplasm or an inflammatory condition

CLINICAL DIAGNOSIS

Osteogenic sarcoma of fibula?
Ewing tumor of fibula?

DR DALAND'S DIAGNOSIS

Ewing sarcoma

ANATOMICAL DIAGNOSIS

Ewing tumor of fibula

PATHOLOGICAL DISCUSSION

DR. MALLORY One of the real problems when a frozen section is done on a bone lesion is that the specimen is likely to contain spicules of calcified material that prevent an adequate section. A frozen section was done during operation on this patient, and the pathologist was certain that the tumor was malignant but uncertain regarding the type, although he favored osteogenic sarcoma because a considerable amount of new-bone formation was recognized. When the final sections came through, however, it was quite obvious that the bone formation was in the stroma and periosteal remnants. No bone was being formed by tumor cells. The latter were of the type characteristic of Ewing tumor, which was the final diagnosis of this case. The tumor had destroyed the lower third of the fibula and had elevated the periosteum as far up as the midpoint of the shaft (Fig 1).

CASE 33162

PRESENTATION OF CASE

A twenty-nine-year-old Italian housewife entered the hospital because of lower abdominal pain, chills and fever.

Four years before entry the patient had had a bout of crampy pain in the right lower quadrant of four months' duration. This was treated conservatively until she had a sudden increase in severity of the pain associated with vomiting, chills, fever and the passage of clots and brownish liquid by vagina, laparotomy was then performed at another hospital. The appendix was found to be retrocecal and held down by a few adhesions but was otherwise normal. The right fallopian tube and right ovary formed an adherent inflamed mass low in the pelvis. When this mass was freed, a few drops of thick pus escaped, this was removed with suction. The markedly swollen and injected right tube was removed. The left tube and ovary were normal. There was drainage from the abdominal wound for five months, but the symptoms were completely relieved. Eighteen months before entry the patient had been delivered of a normal full-term infant. The post-partum course was uneventful. For six months before entry she had had a profuse, malodorous leukorrhea requiring daily douches. Six weeks before entry the last normal menstrual period had occurred. Three weeks before entry she was in a minor automobile accident in which the left lower abdomen was struck against the steering wheel. She suffered no great discomfort from this but noted a slight amount of vaginal bleeding that night and the following day. Six days before entry the patient again had some slight spotting. On the following day, while doing her housework, she was suddenly seized by a violent gniping pain in the left lower quadrant that was severe enough to cause her to lie down,

to "thrash about" and to vomit repeatedly. At the same time she began to pass brownish fluid and blood clots by vagina. After one or two hours of vomiting she fainted, collapsing on the floor. She regained consciousness after a few minutes. A physician was called, and the pain was somewhat relieved by a hypodermic injection, it gradually became less crampy and more general, involving both flanks and the entire lower abdomen. Vomiting and retching persisted, although no food was taken. The patient also continued to have scanty vaginal bleeding. On the day before entry she began to have shaking chills, and temperature rising to 101°F. She had had no pain or burning on urination, frequency or nocturia. The bowels had been regular except for obstipation since the start of the acute episode.

She had begun to menstruate at the age of twelve years, and the periods had always been rather irregular, occurring at an interval of twenty-five to thirty-one days and lasting about three days. She had never lactated properly and had not nursed her last child.

Physical examination revealed a slightly built, poorly nourished woman lying in bed restlessly and complaining of headache and occasional sharp pains in the left lower quadrant. She was somewhat disoriented regarding time. The skin was dry and cool. The lungs were clear. There was moderate diffuse abdominal tenderness most marked in the left lower quadrant, where a vague mass could be felt. The posterior fornix of the vagina was full of dark-brown, liquid blood. The cervix was firm. The uterus was normal in size.

The temperature was 101°F, the pulse 90, and the respirations 20. The blood pressure was 110 systolic, 20 diastolic.

Examination of the blood showed a hemoglobin of 11.0 gm and a white-cell count of 22,200. The urine was normal. The vaginal discharge was negative for beta-hemolytic streptococci and gonococci by smear and culture.

Under penicillin therapy the temperature dropped to normal in three days. On the third hospital day she had another episode of vaginal bleeding, passing clots for an hour and continuing to spot slightly. On the fifth hospital day she was completely free of abdominal complaints. The white-cell count had dropped to 18,800. Two days later, the mass in the left vault was found to be considerably decreased in size, moderately movable and no longer confluent with the uterus.

On the tenth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. FRED A. SIMMONS I am unable to understand, how, with the condition of the patient on admission to the hospital, an operation could have been postponed until the tenth hospital day. The

surgeon had a great deal of courage to wait that long

The history revealed a proved diagnosis of pelvic inflammation, with pus exuding from one tube, three years before the present admission. In spite of that proved pelvic inflammation or salpingitis, a normal full-term pregnancy had occurred eighteen months previously, and the menstrual period was two weeks overdue on admission, although she had been having irregular, spotty vaginal bleeding during the interval.

Five days before entry the patient had an intraperitoneal accident of some kind that was severe enough to cause vomiting, severe pain and unconsciousness. Someone had the temerity to administer a hypodermic injection without operating on her. On the day before admission she had chills and a temperature of 104°F, associated with continuing abdominal pain. On admission a mass was palpated. I am emphasizing these points— inflammatory disease, delayed menstrual period, abnormal metrorrhagia, elevated white-cell count and a mass palpable on abdominal and pelvic examination—because by definition alone it is impossible to rule out an ectopic pregnancy. I believe that it is the policy of the gynecologic service to consider such a condition ectopic pregnancy, and operation was indicated at that time. A possible reason for the delay in operation was that the diagnosis lay between ectopic pregnancy, pelvic inflammation, twisted ovarian cyst and some other pelvic infection, such as tuberculosis, and that the results of the Aschheim-Zondek test were awaited. According to the history the Aschheim-Zondek test could have been negative or positive—negative if there was no viable placental tissue but positive if viable products of conception were still present.

In 1945 at one of these conferences, I discussed the case* of a woman in her thirties with a history of metrorrhagia associated with pelvic findings similar to those in the case under discussion. I failed to make the correct diagnosis, which was tuberculosis of the tubes, because it had not been my experience to find abnormal menstrual bleeding with tuberculosis of the pelvic viscera. The usual history is one of amenorrhea. At any rate, tuberculosis must be considered in this patient because she was described as being poorly nourished and because she had a pelvic infection. About four years ago there was a patient on the wards with a finally proved diagnosis of actinomycosis of the tubes who had some of the same findings—namely, drainage from an abdominal wound for weeks or months following a pelvic operation and a mass, with cachexia, fever and high white-cell count. About thirteen years ago, in the Emergency Ward, a patient was admitted who had had a two-month

history of abdominal pain, flowing and a mass, and for some reason or other no one mentioned ectopic pregnancy. At operation 200 cc of old blood was found in the peritoneal cavity, and the diagnosis of ectopic pregnancy was unmistakable.

The record does not state whether the appendix of the patient under discussion had been removed at the initial operation. If not, one could not fail to consider appendicitis as a cause of the symptoms. The history indicates that the right ovary was not disturbed at the initial operation at which the right tube was removed. Therefore, if the patient had had tuberculosis of the right tube, the other tube or the ovaries, or both, may have been involved. The drainage from the abdominal wound points toward tuberculosis. I paid particular attention to the fact that there was sufficient insult to the peritoneal cavity five days before entry to cause vomiting and unconsciousness as evidence of an acute pelvic process of some kind, such as perforation of a pus-containing sac or a blood-containing sac.

After penicillin therapy, the temperature dropped to normal in three days. If a patient has acute pelvic inflammation and is given chemotherapy, the symptoms subside, the temperature becomes normal, the tenderness disappears and the patient appears well, although a smoldering infection may continue in the adnexa that may flare up weeks, months or years later.

I do not see how we can get away from the facts that the patient was flowing abnormally, that the menstrual period was overdue at the time of admission and that she had a mass. The size of the mass is not described in the record of the pelvic examination, but the statement is made that the mass had "considerably decreased in size" on the seventh day.

As often happens in these conferences the diagnosis entertained on the first reading of the record remains the last, and on the basis of the history and on the physical findings, I must make a diagnosis of ectopic pregnancy.

DR TRACY B MALLORY Dr Sturgis, will you give us your impression of the case?

DR SOMERS H STURGIS I might say that the clinical impression when the patient was first seen was a little more definite than the record indicates, in that the mass was definite, fairly large and fluctuant. On pelvic examination we considered it characteristic of a tubo-ovarian abscess. We were not so impressed as Dr Simmons has been by the overdue period and the bleeding, and I think that we may have missed something. At that time, with the history of inflammation in the past, the clinical appearance of the patient made us think that she had a tubo-ovarian abscess and we were interested to see how it would respond to penicillin. We were pleasantly surprised when the mass decreased in size and became more movable under that treatment.

*Case records of the Massachusetts General Hospital (Case 31152)
New Eng J Med 232:432-434, 1945

DR JOE V MEIGS Is it not true, however, that patients with pelvic inflammatory disease frequently have follicular cysts of the ovary and fall into the group of patients that simulate metropathia, without amenorrhea, followed by bleeding? Is that not characteristic, particularly with chronic pelvic inflammation?

DR STURGIS That is why we did not pay too much attention to the irregularity.

DR MEIGS Dr Younge, do you agree that this case is consistent with the picture one sees with chronic pelvic inflammation?

DR PAUL A YOUNGE Yes

DR MALLORY Will you describe the operative findings Dr Sturgis?

DR STURGIS Operation disclosed a tubo-ovarian mass plastered to the uterus, with dense adhesions. In view of the previous history of five years of inflammation we believed that a hysterectomy was indicated. That is the reason for the removal of the uterus, as well as the mass, which we did not open at operation. We did not suspect anything more than inflammation when the operation was performed.

DR SIMMONS Had the right ovary and the appendix been left in at the first operation?

DR STURGIS The ovary had not been removed, but I cannot remember about the appendix.

DR SIMMONS Was an Aschheim-Zondek test done?

DR MALLORY No

CLINICAL DIAGNOSIS

Tubo-ovarian abscess

DR SIMMONS'S DIAGNOSIS

Ectopic pregnancy, left fallopian tube

ANATOMICAL DIAGNOSES

Acute and chronic salpingo-oophoritis

Placental polyp

PATHOLOGICAL DISCUSSION

DR MALLORY The tubo-ovarian mass was a purely inflammatory lesion, but on opening the uterus we found a small reddish polypoid mass in the fundus, which proved to be a placental remnant. The patient had been pregnant, but it had been an intrauterine rather than an extrauterine pregnancy.

PNEUMOCOCCAL PNEUMONIA

MANY physicians with long experience have been unimpressed with the steady decline in the occurrence of pneumococcal pneumonias in recent years. Although reliable figures of incidence are not available, it is apparent from mortality statistics either that the disease has become less frequent or milder or that modern general management has become increasingly effective, because the decline in mortality antedates the widespread use of recent antibacterial therapy. In Massachusetts, for example, there was a decline of almost 50 per cent in the death rate from pneumonia between 1920 and 1930, as compared with the fairly stable rates recorded in the two preceding decades.¹ In more recent years the drop in mortality has been even more striking. Thus, the deaths from all forms of pneumonia per 100,000 industrial policyholders was 69.8 in 1936, 44.6 in 1940

and 25.9 in 1946, having been 115.2 in 1911.² In the last decade, moreover, pneumonia of all forms (mostly pneumococcal pneumonia) has dropped from third to eighth place among the leading causes of death.³

Unfortunately, accurate figures dealing specifically with large groups of patients with pneumococcal pneumonia are becoming increasingly difficult to assemble. The wide therapeutic range of sulfonamides and penicillin offers too little incentive for the effort required to do careful bacteriologic studies, including pneumococcus typing. Furthermore, these forms of therapy are now generally applied early, as they should be, but bacteriologic studies are all too often undertaken only when the results of therapy do not seem to come up to the physician's expectations. By that time the bacteriologic results may be vitiated by the effects of therapy.^{4,5}

It may not be amiss to point out that it is still important to carry out or at least to obtain materials for bacteriologic studies before treatment with antibacterial agents is begun. The results may prove helpful both in prognosis and in the conduct of the therapy. Although pneumococcal pneumonia can be diagnosed from clinical findings with considerable accuracy,⁶ this may not be true early in the disease, when treatment is most effective both in saving life and in preventing serious complications. The management varies appreciably when a staphylococcus, Friedländer bacillus or *Haemophilus influenzae* is the causative organism. Staphylococcal pneumonias require larger doses of penicillin, and treatment must be continued longer than in pneumococcal cases. The other two forms may not be frequent, but their seriousness, their failure to respond adequately, if at all, to sulfonamides and penicillin and the availability of streptomycin, which may be highly effective if properly used, make it essential to recognize them as early as possible. This can be done only bacteriologically. Gram-stained smears of sputum are simple to make and offer the easiest and fastest means of recognizing the less frequent forms of bacterial pneumonia. The results can then be confirmed by routine cultures. Blood and sputum should therefore be obtained for that purpose before treatment is started, but therapy need not be delayed until the results are available.

A Wright-stained smear of the sputum may also give useful information. The predominance or presence in appreciable numbers of either eosinophils or mononuclear cells, especially if bacteria are absent or scant, suggests a nonbacterial etiology. Eosinophils point to either a parasitic or an allergic agent, and mononuclears, to a viral infection. In either event the failure of antibacterial therapy can thereby be predicted or explained.

The treatment of the patient as a whole, with all his symptoms and manifestations, is still highly important in pneumococcal pneumonia. This is particularly true in infants, in the aged and in those who are severely ill or have serious complications, such as congestive heart failure. One can take little solace from the fact that autopsy reveals no evidence of residual active infection following proper antibacterial therapy in a patient who died of some physiologic disturbance whose correction might have resulted in recovery.

Regarding the optimum specific therapy for pneumococcal pneumonias there is evidence that penicillin is slightly more effective than sulfonamides when used separately⁷ and that both agents, either combined or used to supplement one another, are somewhat more effective than either agent alone.^{8,9} The latter conclusion is based on observations with what may now be considered small doses of penicillin, there being no adequate reports on the use of large doses. For adults, doses equivalent to 30,000 units or more intramuscularly every three hours in early and uncomplicated cases of moderate severity, or up to 100,000 units every three hours in severe bacteremic cases, especially when there are hidden or manifest purulent complications, may give effects that cannot be improved on by the addition of sulfonamides. In meningitis, however, the use of a sulfonamide as an adjunct is probably essential. The possibility of infections with penicillin-resistant strains is still only hypothetical, and sulfonamides would become essential if that eventuality arose. Theoretically, specific antipneumococcus serums should also be helpful, but that has not proved to be true in practice.³

Lest the wrong impression be created, it should be emphasized that the doses of penicillin mentioned are far in excess of those required by the great ma-

jority of patients. For them, as little as 15,000 units intramuscularly every three hours is adequate. The larger doses are needed for the sickest patients, among whom the fatalities are likely to occur. It should be added that oral penicillin in doses of 50,000 or 100,000 units every two or three hours, with care to avoid giving them within one and a half to two hours after a meal, is effective in most cases of moderate severity.^{10,11} Oral therapy may also prove useful in infants and children.¹² Furthermore, daily intramuscular injections of 300,000 units in peanut oil and beeswax may also give a satisfactory result in the average case. In moderately or severely sick patients, however, oral doses cannot be relied on, and the oily preparation should probably not be used or should be given twice a day until the infection has been completely controlled. In all cases, treatment should be continued after apparent recovery with the same or somewhat smaller doses for three to five days, and longer when there are complications.

Repeated local instillations of penicillin into purulent foci afford the most effective therapy for purulent complications, whenever feasible. As much as 50,000 units or even more may be instilled in 10 cc of physiologic saline solution intraspinally or into a joint, and up to 300,000 units in 50 to 100 cc of saline solution may be given intrapleurally each time, the instillations being continued daily in most cases until the infection is well under control. Much smaller doses, however, are usually adequate. Operative drainage can thus be avoided in the majority of cases of empyema.¹³ Systemic therapy is continued, in addition, if the pulmonary infection has not been fully controlled.

The case fatality rates in cases of pneumococcal pneumonia properly treated with sulfonamides and penicillin is now almost zero in young and middle-aged adults and has been reduced to 10 or 15 per cent in those over forty years of age.^{7-9,14}

THE VALUE OF WELL DIRECTED ENDEAVOR

ANNUAL reports are generally written for public consumption. Reading the reports of philanthropic foundations that spend in excess of a million dollars each year may lead one to contemplate the validity of their work—for it is fully as difficult to spend money usefully as it is to make it honestly. Occasionally, the report of a great foundation is tinctured by a sense of humility, and the smallness and the ineffectiveness of what a mere million dollars can buy are thus apparent. The twenty-eighth annual report of the Commonwealth Fund is an example.

The bridge is seldom made between what needs to be done on a large scale and what may be demonstrated in a small pilot study. This is not because the disproportions are so great but rather because the conditions, raw materials and general circumstances cannot be reproduced for the larger applications. We do not fail because we have not been shown how to do things better but because we cannot reproduce in volume the selected circumstances under which we make the initial experiment. Unless we can conduct the trial studies with the same raw materials with which they will later have to be enlarged, we work in ivory towers, however interesting the interiors of these towers may be to the privileged few, the world outside is steered by larger masses. Most foundation boards would agree that the late William H. Welch was an outstanding contributor to the welfare of mankind, but in the recent biography of Harvey Cushing it is related that a Mr. Johnson, Welch's home-town pharmacist, although admitting that "Willy did pretty well down south in Baltimore," thought that he never compared

with his father, a country doctor. There are many more Mr. Johnsons voting than there are directors of foundations, and the experiments of the latter may not be convincing enough to be implemented by the masses on a large scale.

Educators universally encourage the idea that each individual can by aspiration and perspiration raise himself to the top, but their tongues are in their cheeks, with Robert Schumann, they know that "nature would burst should she attempt to produce nothing save Beethovens." Educational institutions also proclaim, with institutional tongues in their cheeks, that they create leaders. They do nothing of the sort. Leaders are born to flourish, some in one environment and some in another, and in a variable but small ratio to the numbers of people whom they lead. An institution that points with pride to its shaping of men's lives is like a person pointing with pride to his parents as if he had personally selected them. Institutions do try to select, but they make conspicuous mistakes and they cannot predict.

Society has an evolving pattern of growth. It seems destined to follow false prophets until it is on the brink of disaster, when the almost superhuman leadership necessary to turn it back toward normal appears. It never quite gets back, however, because there is no agreement about normality. What was normal yesterday is abnormal today, and tomorrow's normal is still different from today's. Is our halting progress due to the fact that we plan on a normality that is evanescent?

In its twenty-eighth annual report, the Commonwealth Fund asks such questions, and it answers them hypothetically by concluding that it is not *how much* it does but what *kind* of things it lays its hand to that really matters.

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

O'HALLORAN—William T. O'Halloran, M.D., of Newtonville, died March 21. He was in his forty-ninth year. Dr. O'Halloran received his degree from Tufts College Medical School in 1924. He was assistant professor of medicine at Boston University School of Medicine, and physician-in-chief, Sixth Medical Service, Boston City Hospital. He was a member of the American College of Physicians, the American Heart Association and the New England Heart Association and a fellow of the American Medical Association. His mother, his widow, a son and five sisters survive.

SANDLER—Frank F Sandler, M.D., of Revere, died March 24. He was in his fifty-seventh year.
Dr Sandler received his degree from Tufts College Medical School in 1915. He was a member of the American Society of Anesthetists and a fellow of the American Medical Association.

His widow, two sons and a daughter survive.

TAYLOR—Lois E Taylor, M.D., of Belchertown, died March 21. She was in her thirty-eighth year.

Dr Taylor received her degree from University of Vermont College of Medicine in 1933. She was a member of the New England Society of Psychiatry and the New England Pediatric Society.

Her father and four brothers survive.

MEDICOLEGAL ABSTRACT

Unauthorized Practice Right of dentist injured by competition of unlicensed practitioner to obtain a court order to prohibit it. A recent New Jersey decision clarifies the function of statutes limiting the right of professional practice to licensed practitioners and the rights that the license confers on them. Two licensed dentists and an association of several licensed dentists sought to enjoin an unlicensed dentist from continuing to practice. The New Jersey statute provided that no one should practice dentistry in that state unless licensed to do so by the State Board of Registration and Examination. The statute provided a money penalty, and a supplement to the statute permitted the Attorney General or the State Board of Dentistry to bring suit to enjoin practice by an unlicensed dentist. The suit was not brought by the Attorney General or the State Board but by licensed dentists who complained that they were losing business and fees because of the unfair and illegal competition of the defendant. They claimed the right to be free from competition from a person practicing without a license.

The court rejected this claim, saying

Prior to the enactment of the dentistry statute no such property right existed. Whether the statute created such right depends upon the purpose for which it was enacted.

I think that the statute in question was passed solely for the protection of the public as against incompetents, and whatever financial benefit results to persons licensed thereunder by the exclusion of unlicensed persons from practicing dentistry is merely incidental, and that the statute was not intended to vest a property right in one licensed thereunder which the licensee is entitled to have protected by a suit of this nature.

The court thus gives a broad indication that a licensed practitioner who is injured by the competition of an unlicensed practitioner has no right on his own initiative, unless the statute gives him one, to have a court eliminate that competition. If the public board or organization cannot be persuaded to take the action they are authorized to take, the injured practitioner has no remedy.

It is well to bear in mind that the statute or circumstances governing another profession or applicable in another state may give the injured practitioner the right that the court holds the New Jersey dentist did not have (*Lipman v Forman*, 138 New Jersey Eq 556).

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

NEW LOCATION OF ANTIPNEUMOCOCCUS SERUM DEPOT

The present procedure for issue of antipneumococcus serum by the Department of Public Health was summarized in the December 12 issue of the *Journal*. The following change has arisen since that time because of the removal of the Bacteriological Laboratory from the State House, the supply of antipneumococcus serum has been transferred to the Division of Biologic Laboratories. Supplies of antipneumococcus serums, Types 1 to 33, inclusive, may be obtained, under the conditions described in the previous notice, from the Division of Biologic Laboratories, 375 South Street, Jamaica Plain 30 (telephone, ARNold 4127). Emergency service is available at all hours.

COMMUNICABLE DISEASES IN MASSACHUSETTS FOR FEBRUARY, 1947

*Three-year median

†Five-year median

COMMENT

Primary interest is again focused this month on diphtheria. The number of cases reported in February is nearly three times that reported during the month of February, 1946, and slightly more than four times the seven-year median. The spread into the Connecticut Valley, noted in January, is continuing and calls for prompt action on immunization in this area to check the spread. The usual seasonal decline is beginning. The highest month was December, with 86 cases, 77 cases were recorded in January.

Chicken pox has shown a sharp increase this month over February, 1946, and is about two times the seven-year median. This is the continuation of the upward swing in the cyclic rhythm that began a year ago.

Diseases above the seven-year median for the month are bacillary dysentery, measles, salmonellosis, pulmonary tuberculosis, undulant fever and whooping cough.

Among the diseases below the seven-year median are German measles, meningococcal meningitis, mumps, lobar pneumonia, poliomyelitis, scarlet fever and typhoid fever.

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Anthrax was reported from Milton, 1, total, 1.

Diphtheria was reported from Amesbury, 1, Boston, 35, Bridgewater, 1, Chicopee, 5, Dedham, 1, Easthampton, 3,

Holyoke, 1, Lowell, 1, Malden, 2, Medford, 1, Natick, 1, New Bedford, 2, Springfield, 2, West Bridgewater, 2, total, 58

Dysentery, amebic, was reported from Boston, 1, total, 1
Dysentery, bacillary, was reported from Worcester, 13, total, 13

Encephalitis, infectious, was reported from Brockton, 1, total, 1

Lymphocytic choriomeningitis was reported from Cambridge, 1, Worcester, 1, total, 2

Malaria was reported from Belmont, 1, Boston, 1, Bridgewater, 1, Cambridge, 1, Medford, 1, Peabody, 1, Southbridge, 1, Westfield, 1, total, 8

Meningitis, meningococcal, was reported from Boston, 3, Brookline, 1, Haverhill, 1, Lynn, 1, Somerville, 1, Waltham, 2, total, 9

Meningitis, Pfeiffer-bacillus, was reported from Boston, 1, Lowell, 1, Medford, 1, Somerville, 1, total, 4

Meningitis, pneumococcal, was reported from Billerica, 1, Boston, 1, Palmer, 1, Salem, 1, Worcester, 1, total, 5

Meningitis, staphylococcal, was reported from Springfield, 1, total, 1

Meningitis, other forms, was reported from Boston, 1, Worcester, 1, total, 2

Meningitis, undetermined, was reported from Cambridge, 2, Lowell, 1, Springfield, 1, Worcester, 3, total, 7

Salmonellosis was reported from Attleboro, 1, Auburn, 1, Haverhill, 1, Melrose, 1, Wellesley, 1, total, 5

Septic sore throat was reported from Boston, 11, Brockton, 1, Fall River, 1, Holyoke, 1, Lancaster, 1, Medford, 1, Newton, 1, total, 17

Tetanus was reported from Chelsea, 1, total, 1

Trachoma was reported from Boston, 2, total, 2

Trichinosis was reported from Boston, 1, Fall River, 1, Quincy, 1, Westport, 1, total, 4

Undulant fever was reported from Leominster, 1, Northampton, 1, Shelburne, 1, Worcester, 1, total, 4

MISCELLANY

NOTES

The following appointments to the teaching staff of Harvard Medical School were recently announced Thomas Gucker, 3rd, of Brookline (A B Princeton University 1937, M D University of Pennsylvania 1941), assistant in orthopedic surgery, Robert Pirrie Woods, of Boston (S B Yale University 1935, M D McGill University 1940), research fellow in surgery, Earl Baker Wert, of Collingswood, New Jersey (M D University of Pennsylvania 1940) assistant in pathology, Peter Hobart Knapp, of Boston (A B Harvard University 1937, M D Harvard University 1941), assistant in psychiatry, Stanley Leonard Robbins, of Brookline (S B Mass Institute of Technology 1936, M D Tufts College 1940), instructor in pathology, Albert Irwin Mendeloff, of Charleston, West Virginia (A B Princeton University 1938, M D Harvard University 1942, M P H Harvard University 1944), assistant in medicine, Curtis Prout, of Dover (A B Harvard University 1937, M D Harvard University 1941), assistant in medicine, Joseph Edward Warren, of Boston (A B Boston College 1934, M D Harvard University 1938), assistant in medicine, Mary Ochsenhirt Amdur, of Somerville (S B University of Pittsburgh 1943, Ph D Cornell University 1946), assistant in ophthalmic research, Toufic Hanna Kalil, of Manchester, New Hampshire (M D Tufts College 1931) assistant in radiology, Jean Patricia Davis, of Rockville, Missouri (A B Smith College 1939, M D Yale University 1943), research fellow in pediatrics, Aniela Stephanie Zygmuntowicz, of Uxbridge (A B Brown University 1938) research fellow in pediatrics, and Fred Ralph Zeiss, of Chicago, Illinois (A A Crane College 1926, B M Northwestern University 1930, M D Northwestern University 1931, S M Northwestern Graduate School 1931), assistant in orthopedic surgery

AUTOMOBILE LIABILITY INSURANCE

According to a letter recently forwarded to members of the Newton Chamber of Commerce, Chapter 614, Acts of 1946, entitled "An Act Relative to Action for Death and Injuries Resulting in Death," drastically changes the present limit of damages in suits for wrongful death. Previous to the passing of this act, which became effective January 1, 1947, the limit

of damages that could be recovered in a suit for the negligent cause of death to a person was \$10,000. This was amended by the 1946 General Court by increasing the amount to \$15,000. In addition, a right is given to sue for "conscious suffering" preceding death. Damages for death are assessed on the degree of culpability of the person causing the death by his negligence, and also according to the pecuniary loss sustained to the parties entitled to benefit by the suit. Previous to this change in the law, damages were assessed according to the degree of culpability only. As a result, it is possible that a motorist in Massachusetts who is involved in an accident in which a person is fatally injured, may find himself liable for damages amounting to \$15,000 or \$20,000.

Since the statutory amount of compulsory insurance remains the same, — that is, \$5,000 liability for damages to any one person, and \$10,000 for each accident, — the average motorist will not be afforded sufficient financial protection by that type of policy. Insurance companies that carry liability coverage are therefore recommending to their policy holders an increase in the amount of liability to \$15,000 for damages to any one person and \$30,000 for damages arising out of any one accident.

BOOKS AND WORLD RECOVERY

The desperate and continued need for American publications to serve as tools of physical and intellectual reconstruction abroad has been made vividly apparent by appeals from scholars in many lands. The American Book Center for War Devastated Libraries has been urged to continue meeting this need at least through 1947. The Center is therefore making a renewed appeal for American books and periodicals — for technical and scholarly books and periodicals in all fields and particularly for publications of the past ten years. Complete or incomplete files of the *New England Journal of Medicine* will be especially welcome.

The generous support that has been given to the Center has made it possible to ship more than 700,000 volumes abroad in the past year. It is hoped to double this amount before the Center closes. The books and periodicals that personal or institutional libraries can spare are urgently needed and will help in the reconstruction that must preface world understanding and peace.

Contributions should be sent to the American Book Center, c/o The Library of Congress, Washington 25, D C, freight prepaid.

BOOK REVIEWS

Preventive Medicine and Public Health. By Wilson G Smillie, M D, D P H, Sc D (hon.) 8°, cloth, 607 pp., with 41 illustrations and frontispiece and 21 tables. New York: Macmillan Company, 1946. \$6.00.

This text gives an excellent summary of the present-day activities of physicians and public-health agencies in the battle against disease, the amelioration of physical and mental handicaps and the promotion of positive health. The picture is painted with broad strokes and with only enough detail to give an adequate understanding of both the problems and the best recognized methods of solution. This makes it possible to cover a wide scope and yet to keep the text handy in size.

The author is a man who has devoted his life to a career in public health, both as a health officer and later as an outstanding teacher, first in Brazil and then at the Harvard School of Public Health and Cornell University Medical College. His interest in field studies did not cease with the beginning of his teaching career. Contributions to epidemiology and public-health administration continue to come from his pen.

Massachusetts readers will recognize the author's loyalty to a pioneer in public health in the quotations from Lemuel Shattuck's report on the sanitary condition of Massachusetts (1850) that grace the beginning of each section. The modern sound of the quotations reminds one of the broad scope of the thinking of the commission that Shattuck headed.

Some specialists will believe that certain sections do not give the latest word regarding their own special field. The terminology is often not the latest. These are inevitable shortcomings of textbooks of broad scope because one man, even with the considerable assistance obtained by the author, cannot be expected to be familiar with the intimate details

of the many special fields. The typographical and editorial errors seem to have been kept at the minimum.

The book not only is valuable in orienting the medical student in preventive medicine but also is a mine of information for the practicing physician and the public-health worker. It will be useful in suggesting sources of public services that patients are often unable to provide for themselves. It should be on the desk of every physician. The readable style, logical arrangement, useful illustrations and excellent type and paper make it a pleasure to use the book.

Hippocratic Wisdom. For him who wishes to pursue properly the science of medicine. A modern appreciation of ancient scientific achievement. By William F Petersen, MD S°, cloth, 263 pp. Springfield, Illinois: Charles C Thomas, 1946 \$5.00

This thoroughly fascinating and scholarly volume is a modern interpretation of ancient scientific achievement, a commentary and interpretation of the Hippocratic texts in the light of present knowledge, for those who wish to pursue properly the study of medicine. The author is particularly interested in the relations of climate and seasons to human disease, and their influence on clinical phenomena. Beginning with "Airs, Waters and Places," he reviews the principal works of Hippocrates, and illustrates their sagacity and truth by applying them to actual case histories of erysipelas, anoxia, miscarriage, epilepsy, rabies, pneumonia, pleurisy, empyema, phthisis, bone tuberculosis, appendicitis, talipes, tetanus and many others. Nearly everything that modern medicine has discovered was foreshadowed, at least *in posse*, by the Hippocratic wisdom. Moreover, the author emphasizes the fact that, in both the theory and the practice of physic, Hippocrates always viewed his problems in the light of the concept of the whole man, not of the disease as a so-called "clinical entity." Only recently has it been realized that from this standpoint alone can disease in human beings be properly appreciated and understood.

Dr Petersen's work is illustrated by an abundance of well chosen figures in the text. It is also illuminated by copious notes gathered into an appendix, which constitutes an invaluable commentary on the text. Finally, there are many bibliographic references, ancient and modern, a glossary and indexes of illustrations and contents. In modest compass, this is a monumental and inspiring book.

Ophthalmology in the War Years. Edited by Meyer Wiener, MD. Volume I 1940-1943. 8°, cloth, 1166 pp. Chicago: Year Book Publishers, Incorporated, 1946. \$13.50

With the support of the National Research Council and through the efforts of a committee under the leadership of Dr Meyer Wiener, with thirty-six able contributors, the ophthalmologic literature of the world during the war years is brought to the elbow of practicing ophthalmologists in the form of two volumes. Volume I reviews over eighty-five hundred important articles published during the years 1940-1945. Volume II, in press, will cover the period 1944-1946. Thus, the ophthalmologists who served in the armed forces and those who served at home are given an unparalleled opportunity to catch up with the advances in ophthalmology.

Great commendation is due the contributors of this valuable review, to the National Research Council and to the publishers for bringing such an important aid and stimulus to the ophthalmologic profession. Every progressive ophthalmologist will either buy these volumes for his working library or combine with his colleagues to obtain the volumes for his local medical library.

Technique of Psychoanalytic Therapy. By Sandor Lorand, MD. 8°, cloth, 251 pp. New York: International Universities Press, 1946. \$3.50

This volume is based on talks that the author has given, especially those at the New York Psychoanalytic Institute. Although it is admitted in the preface that therapeutic achievement may be arrived at "through different avenues of approach," the text follows closely the Freudian school, including dream interpretations, oedipus complex and the couch. If the reader is not orthodox—that is, a heretic—he will find time to do considerable day-dreaming himself while perusing the pages. If one is orthodox, reading will be unnecessary.

The linking of physiologic forces with the psychologic is admitted only because it helps the patient to understand his symptoms.

One patient who fell asleep during the analytical hour is stated to have been expressing "his strong defense against change and fear that his defenses would be broken." Here the interpretation of the psychology of sleep will be new to psychiatrists who have been compelled to give sedatives for the induction of sleep to overcome "defense against change and fear."

"Character neurosis" is not defined clearly but apparently applies to neurotic patients who have resistance to analysis. In dream analysis the author quotes dreams that appear to be unusual to one who has dreamed and who has listened to other people's dreams, and it is stated that "usually there are no indications of feelings in dreams or, if present, they are milder than the patient's actual, repressed feeling associated with the unconscious, latent desire."

The final chapter, on termination of analysis, could not, of course, have given explicit directions. This is a moot problem, even among psychoanalysts.

Report on a Survey of Medical Education in Canada and the United States. By C E Dolman, M R C S (Eng), L R C P, M B, B S, M R C P, D P H, Ph D (Lond), and F A P H A. 4°, paper, 53 pp., with 2 tables. Toronto: University of Toronto, 1946.

Something of the character of the author of this pamphlet is revealed by his biography as reported in *American Men of Science*. He is an Englishman educated in London who has acquired the degrees of Bachelor of Medicine, Bachelor of Science, Doctor of Public Health and Doctor of Philosophy. He worked first as house surgeon and later in research at Saint Mary's Hospital, then he came to Canada, where he engaged in further research at the Connaught Laboratory in Toronto. Finally he moved to Vancouver, where he is now professor of bacteriology and preventive medicine in the University of British Columbia, as well as director of the Provincial Board of Health Laboratories. This record speaks for his industry and competency.

A little over a year ago he was instructed by the Board of Governors of his university to survey medical education in the United States and Canada. He approached the task by visiting eleven representative Canadian schools and twenty-two in the United States. He talked with medical educators as he met them, he received many interesting and varied impressions, and he developed a clear-cut picture in his mind of the main principles and prerequisites of a first-class school. This picture he now attempts to describe in writing.

He emphasizes several points that most medical educators would also stress: the need of university sponsorship for a medical school, of adequate budget and hospital facilities and of a strong faculty guided by a competent dean.

The author is particularly impressed with the need for a school to be intimately associated with a university, to assure, as he expresses it, physical contiguity and spiritual affinity between the faculty of medicine and other university faculties. He believes, with equal firmness, in full-time clinical teaching, the university having complete control of a sufficient number of hospital beds to ensure proper teaching facilities. In his own locality he wishes his school to exert a generally helpful educational influence by providing postgraduate training for practitioners, by improving hospital standards and by developing a close relation with city and provincial health departments.

The report is written intelligently. As the author says, it is likely to be approved in general by educators. Yet, he adds, he is certain that his suggestions will meet strong opposition from certain quarters. He hints that it may be difficult to obtain sufficient funds from the purses of the people to develop and finance a thoroughly sound program of medical education. Good medical education is costly, and not everyone sees the need for it.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Diseases of the Skin. By George C Andrews, MD, associate clinical professor of dermatology, Columbia University College of Physicians and Surgeons, chief of clinic, Department of Dermatology, Vanderbilt Clinic, chief, Derma-

tology Clinic, Roosevelt Hospital, attending dermatologist, Presbyterian Hospital and Roosevelt Hospital, and consulting dermatologist and syphilologist, Tarrytown Hospital, Grasslands Hospital, Valhalla, St. John's Hospital, Yonkers, Greenwich Hospital and Beckman-Downtown Hospital Third edition 8°, cloth, 937 pp, with 971 illustrations Philadelphia and London W B Saunders Company, 1946 \$10 00

Public Health and Welfare Reorganization The postwar problem in the Canadian provinces By Harry M Cassidy, Ph D 8°, cloth, 464 pp Toronto The Ryerson Press, 1945 Cloth, \$4 50, paper \$3 50

Muscle Testing Techniques of manual examination By Lucille Daniels, M A, director and associate professor of physical therapy, Stanford University, Marian Williams, M A, assistant professor of physical therapy, Stanford University, and Catherine Worthingham, M A, director of professional education, National Foundation for Infantile Paralysis, Incorporated 4°, paper, 189 pp Designed and illustrated by Harold Black, with 349 diagrammatic line drawings Philadelphia and London W B Saunders Company, 1946 \$2 50

Electrocardiography in Practice By Ashton Graybiel, M D, Captain, Medical Corps, United States Naval Reserve, coordinator of research, United States Naval School of Aviation Medicine, Pensacola, Florida, and Paul D White, M D, lecturer in medicine, Harvard Medical School, and physician, Massachusetts General Hospital With the assistance of Louise Wheeler, A M, executive secretary, Cardiac Laboratory, Massachusetts General Hospital, and Conger Williams, M D, assistant in medicine, Harvard Medical School and Massachusetts General Hospital Second edition 8°, cloth, 458 pp, with 323 illustrations Philadelphia W B Saunders Company, 1946 \$7 00

Injury and Death under Workmen's Compensation Laws The fundamental principles as interpreted by the courts and compensation experts in all compensation states and in other jurisdictions, including the American territories and England By Samuel B Horowitz, A B, LL B 8°, cloth, 486 pp Boston Wright and Potter Printing Company, 1946 \$6 00

Electrocardiography, including an atlas of electrocardiograms By Louis N Katz, M D, director of cardiovascular research, Michael Reese Hospital, Chicago, and professorial lecturer in physiology, University of Chicago School of Medicine Second edition, thoroughly revised 4°, cloth, 882 pp, with 525 illustrations Philadelphia Lea and Febiger, 1946 \$12 00

Nursing in Commerce and Industry By Bethel J McGrath, R.N., for the National Organization for Public Health Nursing 8°, cloth, 356 pp New York Commonwealth Fund, 1946 \$3 00

Sex, Marriage and Family By Thurman B Rice, M.D., professor of bacteriology and public health, Indiana University School of Medicine 8°, cloth, 272 pp Philadelphia J B Lippincott Company, 1946 \$2 50

Fees and Fee Bills Some economic aspects of medical practice in nineteenth century America By George Rosen, M.D., Ph D Supplement No 6 to the Bulletin of the History of Medicine. 4°, paper, 91 pp Baltimore Johns Hopkins Press, 1946 \$1 50

Water Treatment and Purification By William J Ryan, M E Second edition 8°, cloth, 270 pp, with 66 illustrations New York and London McGraw-Hill Book Company, Incorporated, 1946 \$2 75

Women in Industry Their health and efficiency By Anna M Baetjer, Sc D, assistant professor of physiological hygiene, School of Hygiene and Public Health, Johns Hopkins University Issued under the auspices of the Division of Medical Sciences and the Division of Engineering and Industrial Research, National Research Council Prepared in the Army Industrial Hygiene Laboratory 8°, cloth, 344 pp, with 122 tables Philadelphia and London W B Saunders Company, 1946

NOTICES

ANNOUNCEMENTS

Dr John K. Brines announces the removal of his office to 619 Washington Street, Wellesley

Dr Arthur W Clancy has returned from military service and has resumed practice at 102 High Street, Newburyport, specializing in diseases of the eye, ear, nose and throat.

Dr Henry W Ohrenberger announces the opening of his office at 1101 Beacon Street, Brookline, for the practice of gynecology and obstetrics

GREATER BOSTON MEDICAL SOCIETY

A meeting of the Greater Boston Medical Society will be held in the auditorium of the Beth Israel Hospital on Tuesday, May 6, at 8 15 p m Dr Willem J Kolff, chief of the Department of Medicine, Municipal Hospital, Kampden, Holland, will speak on the subject "New Ways of Treating Uremia"

AMERICAN CONGRESS OF PHYSICAL MEDICINE

The twenty-fifth annual scientific and clinical session of the American Congress of Physical Medicine will be held September 2 to 6, inclusive, at the Hotel Radisson, Minneapolis Scientific and clinical sessions will be given on September 3, 4, 5 and 6 All sessions will be open to members of the medical profession in good standing with the American Medical Association In addition to the scientific sessions the annual instruction courses will be held September 2, 3, 4 and 5 These courses will be open to physicians and therapists registered with the American Registry of Physical Therapy Technicians

For information concerning the convention and the instruction course, address the American Congress of Physical Medicine, 30 North Michigan Avenue, Chicago 2

STREPTOMYCIN TREATMENT OF PULMONARY INFECTIONS*

Clinical and Bacteriologic Studies of Six Cases

H WILLIAM HARRIS, M.D.,† RODERICK MURRAY, M.D.,‡ TOM F. PAINE, M.D.,§
AND MAXWELL FINLAND, M.D.¶

BOSTON

ALTHOUGH pulmonary infections caused by gram-negative bacilli are much less frequent than those caused by gram-positive cocci, they are generally severe and often leave serious damage in the lungs of patients who recover. Their importance has become particularly evident since the advent of the sulfonamides and penicillin, which have produced highly favorable results in pneumococcal, streptococcal and staphylococcal pneumonias but have not materially influenced those due to gram-negative bacilli.

Since the original report by Schatz, Bugie and Waksman¹ on streptomycin and its antibacterial action against certain gram-negative bacilli, numerous studies have confirmed the marked effect of this antibiotic against most gram-negative bacteria including those that cause pulmonary infections.²⁻⁷ There are few reports, however, on the clinical use of streptomycin in pulmonary infections. Herrell and Nichols⁸ treated 5 cases of suppurative disease of the tracheobronchial tree caused by a variety of gram-negative organisms, and obtained good results in 4. Olsen⁹ mentioned briefly the successful use of the antibiotic by nebulization in 9 patients with bronchiectasis who had not responded to penicillin therapy and whose sputums contained a variety of gram-negative organisms. He pointed out that, whereas streptomycin treatment often

eliminated gram-negative organisms from the sputum and thereby reduced both the cough and the volume of sputum, the primary bronchial dilatation was not affected and the patients were still subject to the hazards of a deformed bronchial tree. Durant and his associates¹⁰ reported 3 cases of pulmonary infections caused by *Haemophilus influenzae* that were treated by bronchoscopic instillation of streptomycin, supplemented in one case by parenteral administration. The results were uniformly good. The successful use of streptomycin in the treatment of single cases of pneumonia due to Friedländer bacillus has been reported by Learner and Minnich¹¹ and by Bishop and Rasmussen.¹² The series reported by the Committee on Chemotherapeutics and Other Agents of the National Research Council¹³ includes 44 cases of acute or chronic pulmonary infections caused by various susceptible gram-negative bacteria in which 15 patients recovered, 18 improved and 11 showed no effect from streptomycin therapy. The clinical and bacteriologic observations in 6 cases of pulmonary infections treated with streptomycin are the subject of the present report.

MATERIALS AND METHODS

Patients were chosen for treatment with streptomycin from among regular admissions to the adult medical wards of the Boston City Hospital. They all had acute or chronic bronchopulmonary infections, or both, with various gram-negative bacilli as the only or predominating organisms in the sputums. In each case the organisms obtained before streptomycin treatment were sensitive to concentrations of this antibiotic that could usually be maintained in the plasma. Three patients had acute pneumonia, and the other 3 had chronic bronchopulmonary infections with acute exacerbations. One of the

over the right lower lobe and there were many medium crepitant rales over both lower lobes. A systolic murmur was heard along the right sternal border. The blood pressure was 155/82. The abdomen was distended and tympanic, and there was some tenderness to deep palpation in the left upper quadrant.

Examination of the blood revealed a hemoglobin of 85 per cent (Sahli) and a white-cell count of 8600, with 53 per cent neutrophils, 40 per cent lymphocytes and 7 per cent monocytes. The blood Hinton reaction was negative. The nonprotein nitrogen of the blood was 71 mg per 100 cc. A blood culture was negative, as was urinalysis. A sputum culture showed *H. influenzae* predominating and a few colonies each of *Streptococcus viridans*, *Escherichia coli* and diphtheroids. Roentgenograms of the chest showed thickening of both hilar roots, with infiltration of the surrounding regions. There were multiple nodular areas of density throughout the right middle and both lower lobes and a larger irregular area of density in the right lower lobe. The heart was moderately enlarged, and there was an aneurysmal dilatation of the ascending aorta.

The dehydration was promptly corrected by administration of fluids parenterally, and the blood nonprotein nitrogen dropped steadily to 35 mg per 100 cc. Oxygen was given by nasal catheter with only slight improvement in the cyanosis and dyspnea, and the distention yielded only partially to repeated doses of prostigmine. Penicillin was given intramuscularly at first and then by inhalation. On the 5th day the patient became delirious and unco-operative and it was necessary to discontinue the aerosolization and to readminister the penicillin by the intramuscular route.

On the 7th hospital day the patient was still acutely ill, dyspneic, febrile and completely disoriented. At that time there were signs of consolidation in the right lower lobe and numerous rales at both lung bases. The cough was still severe and productive of large amounts of purulent sputum, cultures of which yielded a pure and abundant growth of *H. influenzae*. These organisms were also seen in large numbers in direct smears of the sputum. The organism was inhibited *in vitro* by 50 units of streptomycin per cubic centimeter. Another blood culture showed no growth.

The penicillin was then stopped, and streptomycin was started. The initial dose was 1 gm intravenously followed immediately by 1 gm intramuscularly every 6 hours for a total of 32 gm. Within 36 hours after the first dose of streptomycin the patient showed decided improvement and became rational and well oriented, and the cough and sputum diminished markedly. On the 14th hospital day, when the streptomycin was stopped, the patient's appetite had returned, and his strength had improved so that he was able to sit up in a chair for several hours each day. The signs in the lungs had also cleared progressively, and only a few crepitant rales were heard, mostly over the right lower lobe. There was irregular fever at first, with a steady rise in temperature during the last 2 days of streptomycin therapy, and a return to normal after the drug had been stopped. Direct smears and cultures of the sputum 24 hours after the first dose of streptomycin and repeatedly thereafter failed to show any *H. influenzae* bacilli. Convalescence was uneventful except for repeated episodes of urinary retention. By the end of the 3rd week the cough had completely stopped and the lungs were clear on both physical and x-ray examination.

The course, therapy and some relevant findings in this case are presented in Figure 1.

CASE 2. A 54-year-old shoemaker entered the hospital on July 3, 1946. He had had an attack of pneumonia 10 years previously and a chronic productive cough since that time. During the year before admission he noted weakness and increasing fatigue. On the day before entry he developed left- and right-sided pleuritic pain. The cough increased, and he began to raise blood-tinged sputum. The patient appeared acutely ill and dehydrated and was coughing frequently and raising tenacious rusty sputum. Dullness, bronchial breathing and crepitant rales in the right lung were the only positive physical findings. The temperature was 102°F, the pulse 100 and the respirations 25. Examination of the blood disclosed a hemoglobin of 75 per cent (Sahli) and a white-cell count of 11,500, with 86 per cent neutrophils. The blood nonprotein nitrogen was

126 mg per 100 cc. A blood Hinton test was positive. Urinalysis was negative. Microscopical examination of the stained sputum showed numerous large encapsulated gram-negative bacilli, and a culture revealed a Type A Friedländer bacillus. A blood culture showed no growth. A roentgenogram of the chest revealed dense consolidation of the peripheral portion of the right middle lobe and of the lower portion of the right upper lobe.

The antibacterial therapy and the course of the disease are shown in Figure 2. The patient was given parenteral fluids and oxygen by nasal catheter. Codeine and Demerol were used to relieve pleuritic pain. Forty thousand units of penicillin was given intramuscularly every 3 hours. On the 3rd hospital day, after adequate hydration had been obtained and the blood nonprotein nitrogen had fallen to 46 mg per 100 cc, the patient was given sulfadiazine in full doses by mouth. In spite of this therapy he showed no clinical improvement. The white-cell count increased. Friedländer bacilli persisted in large numbers in the sputum and an x-ray film of the chest showed extension of the consolidation to the remainder of the right middle and most of the right upper lobes. The penicillin and sulfadiazine were both discontinued on the 6th day, and streptomycin therapy was then begun. The initial dose was 1 gm intravenously and a similar amount intramuscularly and this was followed by 1 gm every 6 hours.

Within 48 hours, the patient appeared less dyspneic and the temperature and pulse rate dropped somewhat. A sputum culture obtained 6 hours after the initial dose of streptomycin showed only 15 colonies of Friedländer's bacillus and this organism was not found in the culture made after the 2nd day of streptomycin therapy. The gross appearance of the sputum however showed no change during this interval. A roentgenogram of the chest on the 4th day of streptomycin treatment showed no extension of the pulmonary process, but small areas of increased radiance were seen within the right middle lobe. In spite of the clinical and bacteriologic improvement the patient expired suddenly on the 4th day of streptomycin therapy after a total of 15 gm of streptomycin had been given.

Autopsy. Post-mortem examination revealed dense gravely consolidation of the right upper and middle lobes and numerous small thin-walled abscesses throughout the consolidated areas. The contents of the abscesses and the alveolar and bronchial exudate were thick mucoid and stringy and yielded Type A Friedländer bacilli on culture. No evidence of embolism was found. The organism obtained at autopsy was inhibited *in vitro* by 0.8 units of streptomycin per cubic centimeter — a value identical with the minimum inhibiting concentration before treatment.

CASE 3. A 54-year-old bartender was admitted to the hospital on September 12, 1946. A week previously he had developed a cold with coryza, and 2 days later he began to have severe pleuritic pain in the right anterior chest and a cough productive of purulent sputum. He had had pneumonia 14 years previously and two brief episodes of pleuritic pain during the preceding 4 years, but there had been no chronic cough or cardiac symptoms.

On admission the patient appeared acutely ill and in a shock-like state, the skin was flushed and moist, the tongue was dry, and the lips and fingernails slightly cyanotic. There were signs of consolidation of the lower half of the right side of the chest anteriorly, and a few medium crepitant rales were heard throughout the left posterior portion. The heart was not enlarged and no murmurs were heard, but the rhythm was totally irregular. The temperature was 98.6°F, the pulse 120 and thready, and the respirations 32 and labored. The blood pressure was 95/55.

Examination of the blood disclosed a hemoglobin of 110 per cent (Sahli), a hematocrit of 45 per cent and a white-cell count of 25,000, with 96 per cent neutrophils, half of which were young forms. The blood nonprotein nitrogen was 42 mg per 100 cc. The blood Hinton reaction was negative. The urine contained a trace of albumin and there were many fine granular casts in the sediment. An arm-to-carotid-sinus circulation time was normal and the electrocardiogram showed only auricular fibrillation.

A blood culture was positive for a Type C Friedländer bacillus*. The sputum was tenacious, purulent and bloody, and a stained smear showed it to contain innumerable large, encapsulated gram-negative bacilli and a few gram-positive lanceolated diplococci. A Neufeld test with anti-pneumococcus serums showed a reaction of some of the diplococci with Type 19 antiserum. Cultures of the sputum on blood-agar plates yielded only Friedländer bacilli, but this organism and a Type 7 pneumococcus were obtained from

after treatment were negative. Friedländer bacilli persisted in the sputum in varying numbers. Pneumococci were looked for in the sputum by all available methods. Type 7 pneumococci were isolated on only one more occasion, but Type 19 pneumococci, which had been seen in the fresh Neufeld preparation of the sputum on admission, were not observed again until they were isolated on the 8th day.

On the 5th day, signs of cavitation of the right middle lobe were made out and confirmed by x-ray study. Because of

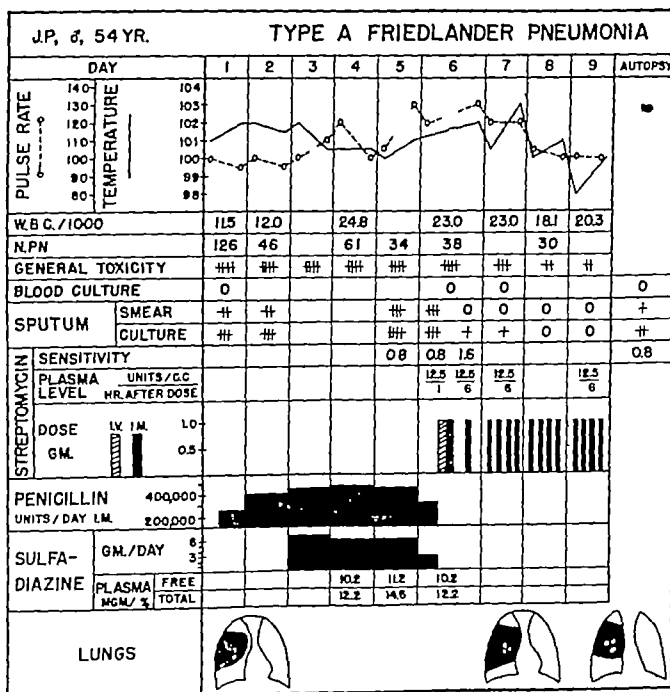

FIGURE 2 Relevant Findings in Case 2

The pneumonia progressed and organisms persisted in the sputum in large numbers during treatment with penicillin and sulfadiazine. Streptomycin therapy was followed by definite clinical improvement and elimination of Friedländer bacilli from smears and cultures of the sputum. The consolidation and abscess formation that are typical of Friedländer pneumonia were found at autopsy in the right upper and middle lobes, and moderate numbers of organisms were obtained in cultures from these lobes. No other cause of the sudden death was found.

cultures of the heart's blood of a mouse inoculated with the sputum.

The patient was given fluids parenterally and by mouth, as well as small doses of morphine and codeine to relieve the pleuritic pain, and digitalization was begun. Because of the characteristic findings in the sputum, a diagnosis of pneumonia due to a Friedländer bacillus was made, and intramuscular streptomycin was begun promptly with 1 gm every 4 hours for 2 days and then every 6 hours for 4 more days. The usual initial intravenous injection was not given in this case because of the danger that a histamine-like reaction would aggravate the shock-like state of the patient.

The therapy, course and bacteriologic findings are presented in Figure 3. The patient's general condition began to improve within a few hours. He then became progressively stronger and more active, the appetite returned, the pleuritic pain diminished, the breathing became easier and the blood pressure rose to 120/80. Auricular fibrillation continued until the 9th day, when normal sinus rhythm was restored. Blood cultures taken on four occasions during the first 2 days

this finding and because of increasing pain and tenderness at the injection sites, the intramuscular administration of streptomycin was discontinued, and subsequent doses were given by the inhalation of 125 mg dissolved in 1 cc of saline solution ten times daily. Each inhalation was preceded by a 5-minute period of postural drainage. On this regime the patient continued to improve, and the number of Friedländer bacilli in the sputum decreased. On the 10th day, because of the persistence of large numbers of Type 19 pneumococci in the sputum associated with a rising temperature, the patient was also given 100,000 units of penicillin intramuscularly every 8 hours. The temperature dropped promptly, and the number of pneumococci in the sputum diminished markedly. Both the penicillin and streptomycin were discontinued on the 17th day. At that time the patient had only a slight residual cough, raised moderate amounts of purulent sputum and had some sweating at night. Roentgenograms still showed the area of consolidation with several small abscesses.

During the next 2 months the patient remained afebrile and symptom free, and regained much weight and strength. The area of pulmonary consolidation diminished in size and showed some evidence of fibrosis. The abscesses became

*The cultures of Friedländer's bacilli in this case were all typed at the Bureau of Laboratories of the New York City Department of Health through the courtesy of Miss Annabel Walter.

radually smaller and finally could no longer be made out. Friedländer bacilli continued to be the predominant organisms in the sputum cultures, but the Type 19 pneumococci could not be isolated after the 3rd week.

The streptomycin and penicillin sensitivities of the various organisms isolated at different times during and after therapy are shown in Figure 3. The Friedländer bacilli (all the strains were Type C) increased in resistance to streptomycin abruptly and markedly on the 3rd day and remained resistant thereafter. The streptomycin sensitivity of the Type 7 pneumococcus was the same before therapy and on the 5th day.

purulent discharge from the left ear, and small perforations were seen in both tympanic membranes. Numerous crepitant rales were heard over the right middle lobe and both lower lobes of the lungs, but no signs of consolidation were made out. The sputum was profuse and mucopurulent.

Urinalysis and the hematologic findings were negative. Repeated blood Wassermann and Hinton tests were positive, but those of the spinal fluid were negative. Roentgenograms of the chest showed mottled densities of the right middle-lung field and peribronchial thickenings in both lower lobes. Films of the mastoid processes revealed thickening of the

FIGURE 3 Relevant Findings in Case 3

The Friedländer bacillus bacteremia cleared promptly, and the patient improved steadily after streptomycin was started. The bacilli persisted in the sputum and became resistant to streptomycin. Both streptomycin-resistant and streptomycin-sensitive strains of Type 19 pneumococci were obtained, but there was no change in the penicillin-sensitivity of any of the strains.

The Type 19 pneumococcus, although seen earlier in the sputum, was not obtained from the cultures at that time and could not, therefore, be tested for streptomycin sensitivity. When isolated for the first time it was found to be totally resistant to streptomycin, but much more sensitive strains of this type were isolated on two occasions during and after the streptomycin aerosolization. The penicillin sensitivity of all the strains of these three organisms remained unchanged throughout.

Case 4 An 18-year-old single clerk had had a productive cough and suppurative otitis media since the age of 4 and a attack of lobar pneumonia at the age of 14. In January, 1946, he was admitted to the hospital with pneumonia due to a Type 4 pneumococcus of both lower lobes and was treated with penicillin and sulfadiazine. At that time she was found to have serologic evidence of syphilis. She made a seemingly uneventful recovery from the pneumonia and was discharged after 17 days, although cough and expectoration continued and numerous crepitant rales were still heard in both lung bases.

In April the patient was readmitted primarily for further penicillin therapy because of the persistence of positive serologic tests for syphilis. Physical examination revealed no evidence of that disease. There was a moderate amount of

petrous bones, with bilateral obliteration of the mastoid cells. Stained smears of the sputum and of the aural exudate disclosed numerous large encapsulated gram-negative bacilli, and cultures of both showed abundant colonies of Type A Friedländer bacilli.

The patient was given a course of penicillin consisting of 20,000 units intramuscularly every 3 hours for 8 days. At the end of that time there were no changes in the pulmonary or aural findings, and Friedländer bacilli were found repeatedly in cultures of the ear and of the sputum. Cultures of these organisms obtained at different times were completely inhibited by 0.8 or 1.6 units of streptomycin per cubic centimeter. Small numbers of *Staphylococcus albus* inhibited by 12.5 units of streptomycin, were also obtained from cultures of the aural discharge.

Streptomycin therapy was begun on the 12th day in an attempt to influence the infection in the lungs and in the left ear. The relevant data are shown in Figure 4. The dose of streptomycin was 0.5 gm in 2.5 cc of physiologic saline solution intramuscularly every 6 hours and 25 mg (25,000 units) in 1 cc of saline solution instilled into the left auditory canal every 8 hours. The intramuscular injections were discontinued on the 4th day because of severe gluteal tenderness, and inhalations of 0.3 gm in 15 cc. of saline were given instead seven times a day for 9 days.

There was a gradual decrease in the amount of cough and sputum after the streptomycin had been started, and the discharge from the left ear stopped completely after the 3rd day. Sputum cultures continued to yield Friedländer bacilli for 4 days, but the numbers of characteristic colonies of this organism on surface plates declined rapidly during that time and then could not be found in the sputum cultures made after the 1st day of aerosol therapy. The strain isolated on the 4th day was inhibited by 25 units of streptomycin per cubic centimeter, representing a thirty-two-fold increase in resistance over that found before treatment was begun. Colonies of *H. influenzae* were isolated from the sputum for the first time on the 4th day of streptomycin therapy and

anterior chest for which a physician prescribed codeine the day before entry she had chills, fever, increased cough and blood-stained sputum.

On admission the patient was acutely ill and in marked respiratory distress. The respiratory excursions of the left chest were restricted, and there were dullness, diminished tactile fremitus, voice and breath sounds and medium moist rales throughout the left lower lobe. The abdomen showed the uterine enlargement of the third trimester of pregnancy.

The temperature was 102.4°F, the pulse 140, and the respirations 30.

Examination of the blood disclosed a red-cell count of 3,830,000, with a hemoglobin of 63 per cent (Sahli), and a

FIGURE 4 Relevant Findings in Case 4

repeatedly thereafter until the last day of that treatment. The organisms required between 5000 and 50,000 units of streptomycin per cubic centimeter for complete inhibition of growth. Cultures of the exudate from the left ear were negative for Friedländer bacilli after the 1st day of streptomycin therapy and for *Staph. albus* after the 3rd day.

The patient was discharged from the hospital after 12 days of streptomycin treatment. At that time the left ear had remained dry, the cough and sputum were markedly decreased, but the auscultatory and roentgenographic signs in the chest were essentially unchanged. Two weeks later she was readmitted to the hospital with lobar pneumonia involving the left lower lobe. A Type 2 pneumococcus was obtained in pure culture from typical rusty sputum. The patient recovered promptly following penicillin therapy. Numerous cultures were negative for both Friedländer bacilli and *H. influenzae* before and during this therapy and during a follow-up period of 2 months. Crepitant rales persisted throughout both lower lobes during this period and roentgenograms continued to show peribronchial thickening.

CASE 5 A 25-year-old married woman in the 7th month of pregnancy, was admitted to the hospital on May 27, 1946. She had had five attacks of pneumonia, a chronic productive cough since the age of 6 and an attack of "pleurisy" in 1945. At the age of 15, she had suddenly had a gross hemoptysis and was studied at another hospital, where a diagnosis of bronchiectasis was made. One week before admission she developed severe and persistent pleuritic pain in the left

white-cell count of 42,700, with 93 per cent neutrophils blood culture was negative. The nonprotein nitrogen was normal. A blood Hinton test and urinalysis were negative. The sputum was mucopurulent and contained no blood and on culture yielded *S. viridans*, *H. influenzae*, *Esch. coli* and occasional colonies of Type A Friedländer bacilli. An x-ray film of the chest showed evidence of some fluid on the left and consolidation in the left lower lobe.

The patient was given oxygen by nasal catheter, morphine initially and then codeine for control of the pleuritic pain and 30,000 units of penicillin intramuscularly every 2 hours. A left thoracentesis, performed on the 2nd day, yielded 150 cc of greenish-yellow, cloudy, malodorous fluid that contained 26,000 pus cells per cubic millimeter. Cultures of the fluid yielded a slowly growing unidentified, gram-negative bacillus. After this thoracentesis 200,000 units of penicillin was injected into the pleural cavity. Another thoracentesis on the 4th day yielded 20 cc of purulent fluid that had no odor and gave no growth. One hundred thousand units of penicillin was injected intrapleurally at that time. Further attempts failed to obtain fluid.

On this regime the patient improved considerably. The temperature, pulse and respiratory rates dropped gradually, and the white-cell count fell to 20,000 but severe cough and profuse expectoration continued. On the 6th day penicillin was given by inhalation as well as intramuscularly, the dose was 25,000 units dissolved in 1 cc of isotonic sodium chloride solution aerosolized every 3 hours. During 1 week of this therapy the patient continued to improve clinically, and

X-ray films of the chest revealed some resolution of the pneumonic process but the severe cough continued and was ill productive of large amounts of greenish purulent sputum. Repeated cultures of the sputum revealed only *H. influenzae* (inhibited by 16 units of streptomycin per cubic centimeter) and *Aerobacter aerogenes* (inhibited by 63 units of streptomycin).

On the 14th day the penicillin by inhalation was discontinued and streptomycin was given by this route in an attempt to diminish the cough and sputum. The dose was 50,000 units in 1 cc of isotonic sodium chloride solution aerosolized five times daily. The administration of 50,000 units of penicillin intramuscularly every 2 hours was continued during the streptomycin inhalation treatment. There was a marked reduction in the cough and sputum within 8 hours after streptomycin was begun and during the last of the 5 days of this therapy it was difficult to obtain sputum for bacteriologic examination. No trace of *H. influenzae* could be found in any of the sputum cultures after the 1st day of streptomycin treatment, *A. aerogenes* likewise disappeared from the sputum for 48 hours but reappeared in small numbers on the 3rd day of treatment. The strain isolated on that day had cultural and biochemical properties identical with those of the pretreatment strains, but it grew in 50,000 units of streptomycin per cubic centimeter. Two subsequent specimens of sputum that the patient was able to produce after therapy also contained small numbers of *A. aerogenes* that were totally resistant to streptomycin.

The streptomycin inhalations were discontinued after 5 days and penicillin aerosolization reinstituted. During the 4th week of hospitalization, the patient had no symptoms, the temperature, pulse and respiration were normal and the white-cell count was 12,000. X-ray films of the chest, however, showed persistence of density in the left lower lobe with marked pleural thickening. On the 29th day the patient left the hospital against advice and subsequent follow-up studies were not possible.

Comment. In this case the relief from the acute pulmonary infection and the probable cure of the putrid empyema must be ascribed largely to the use of penicillin, which was given intramuscularly and by inhalation and, on two occasions, intrapleurally. The pleural exudate, although it yielded a gram-negative bacillus was apparently sterilized on this regime. Streptomycin inhalations were probably responsible for a marked reduction in the cough and expectoration and the rapid elimination of *H. influenzae* from the sputum. *Aerobacter aerogenes*, however, persisted and rapidly became resistant during the streptomycin therapy. The pregnancy was unaffected.

CASE 6. A 44-year-old clerk entered the hospital on December 8, 1945. He had been in excellent health until about 2 years before admission, when he developed a cough that persisted and was productive of yellowish and occasionally blood-streaked sputum. He also began to have moderate dyspnea on exertion. Two weeks before entry he noted an increase in the cough, a reappearance of blood-streaked sputum and some chilliness, fever, malaise and anorexia. High fever, shaking chills and right anterior pleuritic pain began 5 days before admission.

The patient appeared well developed, poorly nourished, anemic and acutely ill. The lips and nail beds were cyanotic. There was moderate clubbing of the fingers. The voice was hoarse, owing to paresis of the left vocal cord. There were typical signs of consolidation of the right lower lobe, and medium crepitant rales and rhonchi were heard over the left lower lobe. The temperature was 102.5°F, the pulse 90 and the respirations 32.

Examination of the blood showed a hemoglobin of 98 per cent (Sahli) and a white-cell count of 16,600, with 84 per cent neutrophils. Blood cultures and urinalysis were negative. Sputum cultures revealed *Staph. albus*, *Micrococcus catarrhalis*, *Streptococcus* and *H. influenzae*. Roentgenograms of the chest showed consolidation of the right lower and middle lobes and patchy areas of density in the left lower lobe.

The antibacterial therapy, the relevant bacteriologic findings and some aspects of the course of the disease over a 20-day period are presented in Figure 5. On admission penicillin was administered by nasal catheter and 20,000 units of penicillin was given intramuscularly every 2 hours. After 10 days the penicillin was discontinued. At that time there

was definite clinical improvement as well as a decrease in the white-cell count and physical signs of resolution in the right lower and middle lobes but the cough continued to be productive of large amounts of purulent sputum.

Three days after the end of penicillin therapy the patient had a shaking chill, the temperature rose to 103°F and all the symptoms recurred. The white-cell count rose to 15,000. A blood culture was negative however and no extension of the pulmonary consolidation could be demonstrated. Sulfadiazine was then given by mouth in a dose of 4 gm followed by 1 gm every 4 hours for 3 days when a generalized scarlatiniform rash appeared. Sulfathiazole in the same dosage was then substituted for the sulfadiazine and penicillin was again given in doses of 20,000 units intramuscularly every 3 hours. The rash was later proved to have been due to barbiturates rather than to sulfadiazine. There was a gradual subsidence of the fever and the acute symptoms and sulfathiazole was omitted after 10 days.

For the next 5 weeks there were no acute symptoms and the temperature remained normal. The patient however lost weight steadily, developed severe night sweats and continued to have severe cough and to produce abundant purulent sputum averaging 150 to 200 cc a day. During that time dietary and vitamin supplements were administered and postural drainage was carried out every 2 hours. Bronchoscopic examination revealed profuse purulent secretions from both lower lobes but no evidence of a tumor stenosis or a foreign body.

During the following 6 weeks the patient was given penicillin by inhalation in doses of 25,000 units at first and later 50,000 units dissolved in 1 cubic centimeter of physiologic saline solution every 3 hours, each dose being preceded by postural drainage. He showed considerable clinical improvement on this regime, his strength and weight increased, and he was able to sit up in a chair and to walk short distances. There was no reduction however in the quantity of sputum raised and x-ray films of the chest revealed marked peribronchial thickening in the right lower lobe and small spotty areas of infiltration throughout the right lower and middle and left lower lobes. These findings were interpreted as indicating advanced bronchiectasis.

During the 15th week the patient suffered a serious relapse. He was seated in a chair when he suddenly became extremely dyspneic and cyanotic and rapidly developed profound shock. Loud gurgling sounds were audible throughout the chest suggesting the presence of acute pulmonary edema but there was no venous distention and an electrocardiogram showed no abnormality except tachycardia. The presence of a ruptured lung abscess appeared likely. The patient was put in a position for postural drainage and 200 cc of yellowish-green malodorous pus immediately drained from the trachea. The foot of the bed was elevated, and he was given oxygen by mask and intramuscular injections of caffeine. Postural drainage was carried out frequently and he was again given 50,000 units of penicillin intramuscularly every 2 hours and sulfadiazine in full doses by mouth. An x-ray film of the chest taken with a portable apparatus showed diffuse haziness and patchy infiltration throughout both lung fields. Cultures of the purulent sputum at that time revealed colonies of *Staph. aureus* and *H. influenzae*, and blood cultures were negative.

The patient remained in a precarious condition for 5 days, but the temperature, pulse and respirations began to drop and the cyanosis lessened. Marked weakness, sweating, anorexia and cough with large amounts of sputum continued. Stained smears of the sputum revealed large numbers of small pleomorphic gram-negative coccobacilli and repeated cultures showed many colonies of *H. influenzae* (sensitive to 16 units of streptomycin per cubic centimeter) with small numbers of *Staph. aureus* colonies (inhibited by 25 units of streptomycin and 7.5 units of penicillin).

Seventeen weeks after admission treatment with streptomycin by inhalation was started with a dose of 250,000 units dissolved in 1.5 cc of physiologic saline solution every 2 hours during the day and every 4 hours at night. Each inhalation was carried out immediately after postural drainage and this therapy was continued for 15 days.

There was no clinical improvement after 5 days of this therapy however and large numbers of *H. influenzae* persisted in smears and cultures of the sputum. After 6 days 1 gm of streptomycin was given intravenously in 20 cc of physiologic saline solution four or five times daily in addition

to the aerosolized streptomycin. It was necessary to administer the intravenous injections at the rate of 1 cc or less a minute, for the patient developed flushing, faintness, headache and vertigo when the drug was given at a faster rate. A total of 33 gm was given intravenously over an 8-day period.

The patient showed no clinical improvement during the 13 days of streptomycin therapy, and he continued to cough up 250 to 500 cc of thick purulent sputum daily. Cultures of the sputum showed a rapid disappearance of the staphylococcus, but *H. influenzae* persisted in almost pure culture. The strain of *H. influenzae* isolated 24 hours after the initial aerosolized dose grew well in the presence of 5000 units of streptomycin per cubic centimeter, and the sensitivity of

the trachea and right main-stem bronchus, with local extension into the mediastinum, chronic pneumonitis of the entire right lung and of the left lower lobe and diffuse bilateral bronchiectasis.

RESULTS

The clinical and bacteriologic results are briefly summarized in Table 1. The first 3 patients received streptomycin for severe pneumonia, which in 2 cases had not responded to treatment with penicillin, supplemented in Case 2 with sulfadiazine.

FIGURE 5 Relevant Findings in Case 6

The bronchopulmonary infection was temporarily and only partially improved by sulfonamides and penicillin. Streptomycin therapy was without effect and resulted in the appearance of resistant bacteria in the sputum. Autopsy revealed a bronchogenic carcinoma in addition to extensive pneumonitis and bronchiectasis.

the remaining strains isolated during treatment ranged from 500 to over 5000 units.

Because of the lack of clinical response and the development of fastness by the organism the streptomycin was stopped. Three days later the patient became acutely ill, with fever, increased pulse and respiratory rates and signs of right lower-lobe consolidation. Sputum cultures yielded colonies of *Staph. aureus* that were not inhibited by 50,000 units of streptomycin and of *H. influenzae* that were inhibited by 500 units. Supportive measures and sulfadiazine were given, but the patient became progressively worse and died at the end of the 20th week.

Autopsy. Post-mortem examination revealed reddish-gray consolidation of all lobes except the left upper one. There was extensive dilatation of all bronchi, whose walls were thin but surrounded by fibrotic tissue. Just above the tracheal bifurcation, there was a fleshy, yellowish mass of tumor tissue that had grown through the tracheal wall and extended down the lateral wall of the right main-stem bronchus. The mediastinal lymph nodes were enlarged, firm and filled with carcinomatous tissue. Cultures from the lungs yielded small numbers of *Staph. aureus*, inhibited by 100 units of streptomycin per cubic centimeter, and a heavy growth of *H. influenzae*, inhibited by 5000 units of streptomycin. The final pathological diagnoses were epidermoid carcinoma of

Case 2 ended fatally, but in all 3 cases there was bacteriologic evidence of improvement after streptomycin had been started.

Case 1 was in an aged patient with an extensive pneumonia due to *H. influenzae*. The prognosis at the beginning of streptomycin therapy was considered poor. Rapid clinical improvement followed soon after treatment with streptomycin had been started. The cough and sputum diminished promptly, and the pneumonic process cleared rapidly and then completely. The strain of *H. influenzae* that had been of relatively low susceptibility before treatment rapidly disappeared from the sputum cultures and did not reappear during the follow-up studies.

Case 2 was a pneumonia due to a Type A Friedländer bacillus in which there was no clinical or laboratory evidence of improvement after five days.

intramuscular penicillin, supplemented during the last three and a half days with oral sulfadiazine. The blood culture was negative before and at the end of this therapy. Streptomycin alone was given intramuscularly, and there was definite clinical and bacteriologic improvement. The patient died suddenly on the fourth day of treatment, and autopsy disclosed anatomic findings characteristic of pneumonia due to Friedländer bacillus, with abscess

purulent sputum. The Friedländer bacillus isolated from the sputum on the third day of streptomycin treatment was highly resistant to the action of this drug, and a similar resistance was demonstrated by all the remaining strains of this organism isolated during and after the streptomycin therapy. Shortly after streptomycin had been given by aerosolization, large numbers of Type 19 pneumococci, also highly resistant to streptomycin, were isolated from the

* For a full description of lung at autopsy. The pretreatment culture of the sputum showed Type A Friedländer bacilli. A minimum inhibiting concentration of 1.6 units per cubic centimeter and *Staph. aureus* with a minimum inhibiting concentration of 12.5 units per cubic centimeter. A strain of the *Staph. aureus* with a minimum inhibiting concentration of 6.25 units per cubic centimeter was obtained on the second

in most of the right upper and middle lobes. Although Friedländer bacilli could not be obtained from the sputum during the last two days of therapy, they were recovered from the lungs at autopsy, and were then found to be as sensitive to streptomycin as the pretreatment strains. Case 3 was one of severe pneumonia due to a Type C Friedländer bacillus with bacteremia. The patient was in a shock-like state and almost moribund at the time of admission. Antibacterial therapy during the early acute stage was limited to intramuscular streptomycin. This produced a prompt clearing of the bacteremia and marked clinical improvement. The pulmonary infection, however, instead of clearing completely, became chronic, and definite abscesses formed. Although the patient was afebrile and free of systemic symptoms for three months after treatment, he continued to cough and to produce large amounts of

sputum. After seven days of treatment with intramuscular penicillin, the numbers of pneumococci diminished markedly, although a few colonies of these organisms and many colonies of Friedländer bacilli were repeatedly found in the sputum cultures made during and after the course of penicillin. It is of interest that, whereas both the gram-positive and the gram-negative organisms became markedly resistant to streptomycin during treatment with this antibiotic, neither strain showed any change in sensitivity to penicillin during or after administration of that agent.

The 3 remaining cases represent chronic and recurrent bronchopulmonary infections in which gram-negative bacilli were found in large numbers in the sputum. The streptomycin was used in these cases in an attempt to reduce the amount of cough and sputum by inhibiting or eliminating the gram-negative flora. Each of these patients had received

a fairly long course of penicillin intramuscularly, and 2 of them had also received that antibiotic by inhalation with only partial or temporary relief before streptomycin treatment was started.

In Cases 4 and 5 definite clinical improvement occurred after the streptomycin had been begun. The cough was markedly reduced, and the small amounts of sputum that the patients continued to raise appeared clear rather than purulent. In Case 4, except during the brief attack of Type 2 pneumococcus pneumonia of the left lower lobe that occurred two weeks after streptomycin treatment, the lung findings were essentially unchanged for three months. In this case a thirty-two-fold increase in streptomycin resistance was demonstrated by the Friedländer bacillus, and a strain of *H. influenzae* isolated during treatment was highly resistant to the action of that drug. Neither of these organisms, however, was recovered from sputum cultures during a three-month period after streptomycin treatment.

Of particular interest in Case 4 was the rapid clearing of the purulent discharge from the left ear following the intramuscular and topical streptomycin therapy. Many different types of local and systemic therapy, including long courses of penicillin and sulfonamides, had previously failed to accomplish this result. The ear remained dry and the cultures free of Friedländer bacilli throughout the follow-up period.

Adequate follow-up studies were not conducted in Case 5, but the lung findings were also essentially unchanged ten days after the conclusion of streptomycin therapy. Small numbers of a resistant strain of *A. aerogenes* were recovered from sputum cultures both during and after treatment.

In Case 6 there was no improvement in spite of large doses of streptomycin intravenously and by inhalation, and the patient died soon after this therapy was concluded. *H. influenzae*, the predominant organism in sputum cultures, persisted throughout the period of therapy. There was a marked increase in streptomycin-resistance of this organism within twenty-four hours of treatment. In this case the chronic pulmonary infection was associated with a bronchogenic carcinoma whose diagnosis had been suspected during life but was definitely established only at autopsy.

Untoward Reactions

These were infrequent and minimal. Pain and tenderness in the region of the intramuscular injections were noted in every case, and in Case 4 the sites became red and indurated. Increasing fever during the latter part of the course of streptomycin in Case 1 was probably due to streptomycin, since the temperature dropped steadily after the antibiotic was discontinued. In Case 6 the intravenous injections were accompanied by faintness, flushing and headache when the solution was given at too

rapid a rate. There were no untoward reactions to the nebulized streptomycin in any of the patients. Disorders of labyrinthine or eighth-nerve function were not observed in these cases.

Streptomycin Levels

In all the patients who received streptomycin by the intravenous or intramuscular route, the levels of streptomycin in the plasma measured at various intervals following individual injections throughout therapy were, for the most part, equal to or higher than the in vitro sensitivity of the infecting organism that had been obtained before treatment. The levels corresponded, in general, to those obtained in other patients receiving similar doses of streptomycin. Progressive increases in streptomycin level in the blood were not observed. Blood obtained from 3 patients during and at short intervals after the aerosolization of streptomycin, when they were not receiving systemic therapy, failed to show detectable amounts of the antibiotic.

DISCUSSION

It is not possible to draw final conclusions regarding the value of streptomycin in pulmonary infections, because relatively few cases have been treated. The clinical results, however, in this small series of cases and in those reported in the literature indicate that some patients with pneumonia and certain others with recurrent or chronic bronchopulmonary infections caused by gram-negative bacilli respond favorably to streptomycin therapy. In some cases this drug seems to be life-saving. There are other patients, however, who seem to derive little or no benefit from large doses of streptomycin and in whom the infection may become or remain chronic or may terminate fatally. In certain cases the poor results may be associated with the rapid development of streptomycin fastness by the infecting organisms.

The recovery of streptomycin-resistant bacterial strains during and after treatment in patients with urinary-tract infections,^{14, 16-18} meningitis,^{6, 7, 19} tuberculosis,²⁰ osteomyelitis²¹ and ozena⁹ has been reported, but the same phenomenon has not been described in pulmonary infections due to gram-negative bacilli. Ten separate bacterial strains were isolated from the sputum of these 6 patients before streptomycin treatment was begun, and a significant increase in resistance to streptomycin occurred in 5 during or after the course of therapy. Nine strains of organisms not isolated before therapy were first obtained from cultures of the sputum during the course of streptomycin treatment in 2 cases. Both strains were also highly resistant to the action of the drug. The appearance of resistant bacteria during therapy may be an important factor in determining the eventual clinical results. In Case 6 streptomycin resistance developed rapidly and there was no beneficial effect from the treatment.

Case 3 there was a good clinical response initially, but a streptomycin-fast strain developed and the pulmonary infection became chronic.

The development of drug fastness by the infecting organisms, however, is not the sole factor in determining the clinical result. In 2 cases of bronchiectasis and in a severe case of pneumonia due to Friedländer bacillus there was marked symptomatic improvement despite the appearance of streptomycin-fast strains in sputum cultures. A third patient died of pneumonia caused by Friedländer bacillus during the course of therapy and the strain recovered from the lung at autopsy was identical in its streptomycin sensitivity with the one obtained before treatment.

The basic conditions that give rise to the development of resistance are virtually unknown and it becomes difficult to understand why certain cases show the development of resistant strains and others do not. Two of these cases (Cases 2 and 3) were clinically and bacteriologically similar and both had acute pulmonary infections that appeared to be similar in location and extent, the strains of Friedländer bacillus isolated in each case before treatment showed identical sensitivities to streptomycin by the method used, and the doses of streptomycin were comparable. Nevertheless, the Friedländer bacillus in Case 3 became streptomycin resistant, whereas a similar organism in Case 2 retained its original sensitivity.

Another point worth mentioning is the wide differences in sensitivity of strains of the same organisms isolated at different times after resistance had developed. This suggests that organisms of different resistance coexist in the same exudate and that, since single-colony cultures are tested, the sensitivity of the particular strain tested may be only a matter of chance.

It has been suggested that the maintenance of an alkaline reaction during treatment of urinary-tract infections enhances the antibiotic activity of streptomycin and thereby prevents or curtails the development of bacterial resistance.^{14, 18} Offhand, it does not seem feasible to maintain an alkaline reaction in the infected tissues and exudate in pulmonary infections.

The mortality rate in pulmonary infections due to gram-negative bacilli is high even with the best forms of therapy. Bronchiectasis caused by gram-negative bacilli is often progressive and refractory to the usual antibiotic and chemotherapeutic treatment, and is not always amenable to surgery. Prolonged courses of sulfonamides and penicillin are helpful in some cases. Streptomycin, however, appears at present to be the therapy of choice in such cases, although as in the streptomycin treatment of other infections, clinical failures may result. Obviously, it cannot be expected that the structural damage in chronic cases will be repaired, but healing

may be promoted by the reduction in or the elimination of the infection in such cases. In patients with abscesses or with large bronchiectatic cavities streptomycin by inhalation preceded each time by postural drainage may be the method of choice when susceptible gram-negative bacilli are present in abundance. The inhalations should probably be supplemented by systemic therapy, particularly if there is an accompanying acute pneumonitis.

The favorable results in cases of pulmonary and meningeal infections with *H. influenzae* suggest a possible use of streptomycin in certain severe epidemics of virus influenza in which pulmonary infections are associated with that organism. There is reason to believe that most of the fatal pulmonary complications of epidemic influenza are due not to the virus alone but to its association with hemolytic streptococci, staphylococci, pneumococci and influenza bacilli. Penicillin and sulfonamides should prove effective in cases in which gram-positive cocci are involved, and streptomycin may fill the gap in those due to *H. influenzae*, which is only slightly — if at all — affected by the other agents.

SUMMARY

Three cases of acute and 3 of chronic pulmonary infections caused by gram-negative bacilli are presented, and the clinical and bacteriologic results of treatment with streptomycin outlined. The results of therapy were favorable, although not uniformly so. One of the causes of clinical failure appears to be the rapid development of streptomycin resistance by the infecting organisms. In 1 case drainage from a chronic suppurative otitis media stopped promptly after systemic and local streptomycin therapy.

a fairly long course of penicillin intramuscularly, and 2 of them had also received that antibiotic by inhalation with only partial or temporary relief before streptomycin treatment was started.

In Cases 4 and 5 definite clinical improvement occurred after the streptomycin had been begun. The cough was markedly reduced, and the small amounts of sputum that the patients continued to raise appeared clear rather than purulent. In Case 4, except during the brief attack of Type 2 pneumococcus pneumonia of the left lower lobe that occurred two weeks after streptomycin treatment, the lung findings were essentially unchanged for three months. In this case a thirty-two-fold increase in streptomycin resistance was demonstrated by the Friedländer bacillus, and a strain of *H. influenzae* isolated during treatment was highly resistant to the action of that drug. Neither of these organisms, however, was recovered from sputum cultures during a three-month period after streptomycin treatment.

Of particular interest in Case 4 was the rapid clearing of the purulent discharge from the left ear following the intramuscular and topical streptomycin therapy. Many different types of local and systemic therapy, including long courses of penicillin and sulfonamides, had previously failed to accomplish this result. The ear remained dry and the cultures free of Friedländer bacilli throughout the follow-up period.

Adequate follow-up studies were not conducted in Case 5, but the lung findings were also essentially unchanged ten days after the conclusion of streptomycin therapy. Small numbers of a resistant strain of *A. aerogenes* were recovered from sputum cultures both during and after treatment.

In Case 6 there was no improvement in spite of large doses of streptomycin intravenously and by inhalation, and the patient died soon after this therapy was concluded. *H. influenzae*, the predominant organism in sputum cultures, persisted throughout the period of therapy. There was a marked increase in streptomycin-resistance of this organism within twenty-four hours of treatment. In this case the chronic pulmonary infection was associated with a bronchogenic carcinoma whose diagnosis had been suspected during life but was definitely established only at autopsy.

Untoward Reactions

These were infrequent and minimal. Pain and tenderness in the region of the intramuscular injections were noted in every case, and in Case 4 the sites became red and indurated. Increasing fever during the latter part of the course of streptomycin in Case 1 was probably due to streptomycin, since the temperature dropped steadily after the antibiotic was discontinued. In Case 6 the intravenous injections were accompanied by faintness, flushing and headache when the solution was given at too

rapid a rate. There were no untoward reactions to the nebulized streptomycin in any of the patients. Disorders of labyrinthine or eighth-nerve function were not observed in these cases.

Streptomycin Levels

In all the patients who received streptomycin by the intravenous or intramuscular route, the levels of streptomycin in the plasma measured at various intervals following individual injections throughout therapy were, for the most part, equal to or higher than the *in vitro* sensitivity of the infecting organism that had been obtained before treatment. The levels corresponded, in general, to those obtained in other patients receiving similar doses of streptomycin. Progressive increases in streptomycin levels in the blood were not observed. Blood obtained from 3 patients during and at short intervals after the aerosolization of streptomycin, when they were not receiving systemic therapy, failed to show detectable amounts of the antibiotic.

DISCUSSION

It is not possible to draw final conclusions regarding the value of streptomycin in pulmonary infections, because relatively few cases have been treated. The clinical results, however, in this small series of cases and in those reported in the literature indicate that some patients with pneumonia and certain others with recurrent or chronic bronchopulmonary infections caused by gram-negative bacilli respond favorably to streptomycin therapy. In some cases this drug seems to be life-saving. There are other patients, however, who seem to derive little or no benefit from large doses of streptomycin and in whom the infection may become or remain chronic or may terminate fatally. In certain cases the poor results may be associated with the rapid development of streptomycin fastness by the infecting organisms.

The recovery of streptomycin-resistant bacterial strains during and after treatment in patients with urinary-tract infections,^{14, 16-18} meningitis,^{6, 7, 19} tuberculosis,²⁰ osteomyelitis²¹ and otitis media⁹ has been reported, but the same phenomenon has not been described in pulmonary infections due to gram-negative bacilli. Ten separate bacterial strains were isolated from the sputum of these 6 patients before streptomycin treatment was begun, and a significant increase in resistance to streptomycin occurred in 5 during or after the course of therapy. No strains of organisms not isolated before therapy were first obtained from cultures of the sputum during the course of streptomycin treatment in 2 cases. Both strains were also highly resistant to the action of the drug. The appearance of resistant bacteria during therapy may be an important factor in determining the eventual clinical results. In Case 6 streptomycin resistance developed rapidly and there was no beneficial effect from the treatment.

SENSITIVITY TO PORK-LIVER EXTRACT IN PERNICIOUS ANEMIA*

Clinical Observations on Fourteen Patients

JOHN L BAUER, M D,† R JANET WATSON, M D,† JOHN R CHAMBLISS, M D,†

AND CHARLES S DAVIDSON, M D §

BOSTON

NOT until several years after the classic report of Minot and Murphy¹ on the treatment of pernicious anemia with liver was a potent injectable liver extract first employed for the routine therapy of this disease. In 1933 Gänsslen² gave scant details of the method of preparation but described striking hematologic and clinical effects with the product later well known under the proprietary name of "Campolon." Subsequently, the cases of at least 175 patients who were sensitive to liver extract have been reported, half of them in the last three years. Individual studies indicate that such sensitivity is not a rare condition. Delikat³ reported 14 cases, Feinberg, Alt and Young⁴ recently reported 8 cases, McSorley and Davidson⁵ encountered 40 cases in the past ten years, Kaufman, Farmer and Reich⁶ reviewed 11 cases and Schwartz and Legere⁷ observed 68 cases in 396 outpatients. In view of the number of recent reports, it is apparent that sensitivity is an important complication in patients receiving liver-extract therapy.

This report is based on 14 patients discovered in the past two and a half years to be sensitive to injections of liver extract. The total number of patients under observation during this period was about 200. The clinical manifestations of sensitivity exhibited by the patients can be divided into three varieties. The most frequent effect consisted of generalized itching, urticaria, edema of the face and lips, nausea and vomiting. The second type exhibited peripheral vascular collapse, including thready pulse, sweating, cyanosis, weakness and fainting. A third group of patients manifested local

signs that may have been due to an Arthus type o sensitivity consisting of swelling, itching and in duration without necrosis at the site of injection. Only one patient suffered from asthma. In all cases the immediate symptoms were relieved, at least in part, by the injection of adrenalin.

The maintenance of adequate parenteral therapy with liver extract in sensitive patients may be a difficult problem. In the cases discussed below subsequent reactions were prevented by the employment of an injectable liver extract prepared from another animal source. This success occurred in many cases without complete correlation with the sensitivity as demonstrated by skin tests.

MATERIALS AND METHODS

The purified liver extract containing 15 U S P units per cubic centimeter that had been routinely used in the treatment of patients who had become sensitized was prepared from pork liver, as are apparently, the majority of liver extracts on the market at present. The injectable liver extract employed for testing for sensitivity and administered subsequently by intramuscular injection were prepared from pork, beef and lamb and were of two potencies crude (2 U S P units per cubic centimeter) and purified (15 U S P units per cubic centimeter).¶ For skin testing the extracts were diluted under sterile conditions with physiologic saline solution in the proportions of 1:100 and 1:1000. The special muscle extracts used for skin testing were made from pork, beef and lamb muscle. They were employed undiluted and also diluted with physiologic saline solution in a proportion of 1:10.

All skin tests were performed after the patient had developed sensitivity to pork-liver extract and during the course of therapy with beef-liver extract. They were done by the intracutaneous injection of

tively weak reactions obtained with muscle extracts, we believe that no confirmatory evidence of species specificity can be derived from them.

There is a difference of opinion in the literature regarding the cause and nature of the sensitivity to intramuscular liver extract. In contrast to our experience, most authors favor Cnep's⁸ impression that the sensitivity is primarily of organ specificity, and all agree that it represents an acquired type of sensitivity. Cnep based his conclusions on the fact that he obtained positive skin tests with liver extracts derived from hog, beef, sheep and chicken and negative tests when muscle extracts from the same animals were used. He believed that the sensitivity was to the liver proteins themselves. Andrews⁹ suggested that the allergenic factor was the antianemic principle itself and that changing the animal source of the extract would not eliminate sensitivity reactions. Kaufman, Farmer and Reich⁶ reported observations on 11 sensitive patients in whom the skin tests indicated that the sensitivity was to the organ and not to the animal. Feinberg, Alt and Young⁴ concluded, in the 8 cases that they studied, that the sensitivity was to a special organ fraction associated with the antianemic factor. They reported a patient, however, who was able to tolerate intramuscular injections of beef-liver extract but not of extract derived from pork liver. Engelhardt and Derbes¹⁰ suggested that reactions in some cases were due to impurities but that in general the sensitivity was to the organ and not to the animal from which the extract had been prepared.

On the other hand, there is evidence in the literature to support our conclusion that biologic specificity is a significant — if not the most important — factor in sensitivity to liver extract. Rynes and Tocantins,¹¹ in an excellent review of the literature on sensitivity to liver extract, presented the case of a patient who was able to tolerate beef liver extract but when given pork-liver extract exhibited an Arthus type of sensitivity. Nausea was induced when this patient was given pork to eat. Skin tests, however, were positive for liver and muscle extracts of pork, beef and lamb. The authors concluded that the cases represented a biologic type of sensitivity. In 2 cases reported by Jones¹² 1 patient tolerated without difficulty intramuscular injections of liver extract prepared from beef but reacted severely to an extract of pork origin. Skin tests, however, as in our Case 2, indicated that the patient was sensitive to both liver extracts. Later, the patient was given a horse-liver extract without difficulty. In a patient reported by Bynum,¹³ sensitivity first ap-

peared after eleven injections of an extract, Reticulogen (Lilly), stated to be prepared from pork. The patient tolerated without difficulty injections of an extract derived from beef liver.

Most authors who explain liver-extract sensitivity by organ specificity base their conclusions on the results of skin tests with liver and muscle extracts. From an analysis of the cases included in this report, it is evident that the change in therapy to an extract from a different animal source resulted in the abolition of sensitivity symptoms regardless of the results of the skin tests. Sensitization to liver extracts derived from pork rather than from beef liver predominates in all probability because most of the commercial extracts used in this country are derived from pork liver. Certainly some persons may have an organ-specific sensitivity but no such cases were encountered in our series.

SUMMARY

Fourteen cases of acquired sensitivity to a pork-liver extract given intramuscularly are reported. Symptoms of sensitivity were abolished by a change of the therapy to an extract derived from beef liver.

Skin tests with liver extracts derived from pork, beef and lamb indicated in general greater sensitivity to extract of pork liver than to that of beef and lamb liver.

In the cases studied, clinical experience consistently — and skin tests to some extent — indicated that the sensitivity to liver extract represented an acquired type of species rather than one of organ specificity.

from 0.01 to 0.02 cc of the preparations mentioned above. Sterile physiologic saline solution was used as the control. Nearly all the skin tests were made by the same person and were read at intervals of five, ten, twenty and thirty minutes. The tests were interpreted as follows: 0 = negative (same as control), + = small regular wheal with slight erythema, ++ = moderate-sized wheal (up to 10 mm in diameter) with definite erythema, +++ = irregular wheal over 10 mm in diameter, without definite pseudopods but with definite erythema, and ++++ = large wheal with definite pseudopods and erythema. The results of the tests are presented in Table 1. The symbols given in the table represent the maximum reaction noted. Most authors agree that the presence of pseudopods constitutes a definitely positive skin test. On the basis of our criteria, however, both +++ and ++++ reactions were considered indicative of sensitivity.

RESULTS

After four to eighteen or more monthly intramuscular injections, the 14 patients became sensitive to the purified extract containing 15 USP units per cubic centimeter and prepared from pork liver. The clinical information in these cases is summarized in Table 2.

None of the patients who became sensitive to liver extract prepared from pork experienced distressing symptoms when given an extract derived from beef liver. This change was made after reactions had occurred on one to eighteen occasions, or more, following the intramuscular administration of the commercial pork-liver extract. In 11 of the 14 cases (Cases 1, 4-10 and 12-14) this change in therapy completely — and so far, permanently — abolished all signs or symptoms of sensitivity. In Cases 3 and 11, however, after the eighth and tenth monthly injections of the beef-liver extract, respectively, itching of the palms occurred. Thereupon, both patients were desensitized by initially small (0.1 cc) and gradually increasing (up to 1.0 cc) weekly injections of the beef-liver extract. No further reactions occurred with subsequent monthly injections. Following the thirteenth injection, the patient in Case 2 experienced itching of the palms. She was apprehensive concerning another severe reaction and for this reason refused further injections. Consequently, desensitization was not possible. She is now being successfully treated with an orally administered liver extract prepared from pork. Two of the patients sensitive to pork-liver extract were given beef-liver extract initially in small doses, with an increase at weekly intervals to 1 cc. This was done as a further precaution, since the reactions to the pork-liver extract had been extremely severe.

The patient in Case 10, having been found sensitive to pork-liver extract and having been shifted to beef-liver extract, was subsequently given by

error an injection of 1 cc of a liver extract derived from pork. This was immediately followed by a severe reaction characterized by generalized itching, nausea, vomiting, feeble pulse and weakness. Treatment with beef-liver extract was subsequently resumed without difficulty.

The patients sensitive to liver extract prepared from pork who were skin tested, with one possible exception, exhibited greater sensitivity by this procedure to pork-liver extract than to extracts of beef or lamb liver (Table 1). The few skin tests with allergenic muscle extracts prepared from the same animal sources were negative or only questionably positive in most cases. In Case 6, although the patient was sensitive to pork-liver extract clinically and on the basis of skin tests, reactions with pork-muscle extracts were negative and those with lamb-muscle extracts were positive. In the other patients tested with the muscle extracts a greater sensitivity to pork muscle was observed.

It is difficult to correlate the clinical severity of the reactions with the results of the skin tests. Case 1 provided the most striking example of this discrepancy. In spite of severe reactions clinically, skin tests with pork-liver extract showed only moderately positive reactions. Only 1 patient (Case 6) gave a history of other allergic tendencies. She stated that she was unable to tolerate aspirin, codeine or barbiturates. She gave no history of asthma or hay fever.

As pointed out by many other investigators, the duration of therapy before symptoms of sensitivity appear varies tremendously. In the present series initial symptoms of sensitivity developed earliest after the fourth injection and at the latest after eighteen or possibly more injections over a period of years. The duration and the amount of treatment before the onset of reactions had no apparent relation to the severity of the symptoms.

Thirteen of the 14 patients included in this report were women. The frequency of liver-extract sensitivity among women has been observed by others. Kaufman, Farmer and Reich⁶ reported that 70 per cent of all recorded cases had occurred in females.

DISCUSSION

In treating patients with pernicious anemia who became sensitive to pork-liver extract, we were usually able to eliminate manifestations of sensitivity by changing the therapy to an extract derived from beef liver presumably by about the same method. This suggested that the sensitivity was of species-specific rather than organ-specific type, since the patients would otherwise have suffered further reactions when beef-liver extract was substituted for that derived from pork liver. The results of the skin tests in general confirmed this hypothesis. The majority of the patients showed a greater sensitivity to extracts of pork liver than to those of beef or lamb liver. Because of the rela-

often be cured, or at least arrested, if treated in time

The Commonwealth has assumed responsibility for the care of cases of communicable disease for over half a century. Automatically, as soon as the Department of Public Health declares a disease to be dangerous to the public health, the local board of health becomes responsible for the care of the patient, provided he is unable to pay for treatment himself. If the patient with a communicable disease is a state settled case, he becomes the responsibility of the Department of Public Welfare. The local boards of health and of welfare have been giving medical care on the local level for many years.

The Department of Public Health also furnishes treatment for cases of venereal disease. It maintains twenty-five clinics, which co-operate with the local hospitals. Moreover, free transportation is furnished, if necessary. It provides specific drugs, including the sulfonamides, free of charge to private practitioners for the treatment of venereal diseases, but the physician must be remunerated by the patient for the services he renders, penicillin is furnished without cost to the Co-operating Venereal Disease Clinics.

Another series of clinics that the Department of Public Health sponsors are those for crippled children. These clinics care for any child whose family cannot afford the expensive and long-continued medical treatment necessitated by his crippled condition. All such cases are referred by the family physician or some social agency. A new project is now under way for the care of patients with rheumatic fever. Facilities that have been made available at the North Reading State Sanatorium will make it possible to proceed as soon as adequate personnel is available.

The Commonwealth has been reasonably successful in controlling infectious diseases. In the days of Paul Revere the normal life expectancy was thirty-five years. Today it is sixty-five, and in the near future it will probably be extended to seventy-five. Not much has been accomplished, however, in the care of the chronically ill. Plans are being drawn up for a new chronic-disease hospital at Stoneham, which will accept three types of patients: those in need of hospitalization, those whose treatment will contribute to knowledge of the disease and of methods for diagnosis and treatment, and those with cases that will furnish instruction for doctors and students in the various aspects of the disease. This will not be a custodial institution, but every effort will be made to get the patient on his feet so that he may be discharged. There will also be a large outpatient clinic. Patients will be admitted to this hospital under the same conditions as those governing the admission of cancer patients, few of whom pay any part of their expenses.

* * *

Public health has made outstanding progress in the prevention of disease, and in the phases of medi-

cal care mentioned above. In spite of the fact, however, that well administered health departments are an accepted part of state government, approximately a third of the nation's population are actually living in communities not covered by public health services. Thus, many citizens of the Commonwealth are deprived of the benefits of the latest developments of medical science and preventive medicine. One of the major problems in Massachusetts is the establishment of adequate local health facilities for all the people. Only by the provision of such facilities under the direction of a full-time, trained and experienced health officer can the citizens of any area attain the greatest benefits from sanitation, prevention of communicable diseases, adequate nutrition and all the other factors that ultimately, in their full utilization, bring about the achievement of optimal health. The national welfare demands that the people in small towns receive the same benefits as those in large cities.

Perhaps a definition of the term "optimal health" should be given. If a person is enabled to develop his physical and mental health to the highest degree and to maintain them at high level, he has achieved optimal health — in other words, he is given the opportunity to develop and to utilize the potentials with which Nature has endowed him so as to obtain satisfaction from life and to contribute the greatest effort to the community. Optimal health, therefore, is the summation of the achievements in all spheres of the medical sciences and the healing arts that bring about the greatest happiness, the greatest utilization of one's abilities, the longest life span and the greatest good to the individual, his family and his community.

The responsibility for making available these benefits of medical science and the healing arts rests first with the family, secondly with the official community agencies and thirdly with the voluntary agencies. The health of a person is essentially his responsibility — only if he neglects his health or if his illness adversely affects the community in which he lives does he become a problem of the community. Leaders in the field of public health believe in the rights of individuals. They believe that medical care is a man's own responsibility, just as his family is his responsibility, he should provide such care if he able to do so. Neglect of his health may be due to carelessness and to lack of consideration for his family and his neighbors or to inability to obtain adequate means of prevention or of treatment. Whenever an illness affects other members of the community, health is no longer a purely personal problem but becomes the responsibility of the community as well. The provision of medical care for a patient who has scarlet fever is a family obligation, but his isolation and the quarantine of his contacts are the responsibility of the community. If the family is unable to provide adequate care, the community must meet the need.

THE COMMONWEALTH'S HEALTH PROGRAM

VLADO A. GETTING, M.D., D.R.P.H.*

BOSTON

GOOD health has always been one of man's most prized possessions. From the most primitive times he has endeavored to take advantage of such knowledge as was available to him in prolonging his life, in preventing disability and in avoiding sickness. Believing that disease was of demonic origin he employed various mystic incantations in an attempt to ward off and to cure illness. The Mosaic laws contain the first rudimentary development of a definite sanitary code. Not until relatively modern times, however, could advantage be taken of accurate scientific knowledge in the prevention of disease, the prolongation of life and the attainment of optimal health.

Massachusetts has always been one of the pioneers in the field of public health. About two hundred years ago, Boston passed its first ordinance for the purpose of quarantining ships entering the harbor from ports where diseases such as yellow fever and smallpox were prevalent. Approximately twenty-five years later, the ubiquitous Paul Revere, who not only completed his famous ride but also made George Washington's false teeth, became chairman of Boston's first board of health. In 1869 the first state department of health in this country was created in Massachusetts. Since then, official health departments have been extended throughout the entire country.

* * *

In medical care, Massachusetts has also taken the lead and has supported certain phases of so-called "state medicine" for over a hundred years. At present there are no less than seven departments of the state government taking an important role in medical care. Of primary significance are the boards of registration that, through the licensing of doctors, dentists, pharmacists and nurses, attempt to ensure quality in medical practice. Unless there are adequate standards for practitioners, there cannot be adequate medical care. Although the Approving Authority for medical schools has now made it impossible for graduates of unapproved schools to take examination for licensure in the Commonwealth, it must be remembered that, in Massachusetts, approximately fifteen hundred graduates of substandard schools are at present engaged in active practice.

Two groups are interested in the medical care of the worker in industry. The Industrial Accident Board is concerned with the medical and hospital care of workers injured on the job, whereas the Division of Occupational Hygiene in the Depart-

ment of Labor and Industries studies the health hazards that the worker encounters.

The Department of Public Welfare not only maintains the State Infirmary at Tewksbury and the Massachusetts Hospital School at Canton for the custodial care of crippled and deformed children but also finances the medical care of indigent persons suffering from diseases that are not communicable. The Vocational Rehabilitation Program, under which any person of legal employable age who is totally or partially incapacitated for remunerative occupation may obtain assistance, administered by the Department of Education. In case of financial need, the corrective medical, surgical or psychiatric treatment required to make it possible for the patient to obtain employment is provided. For example, if a man has a hernia that interferes with his ability to work, he may have it repaired. The Department of Mental Health, which has perhaps the largest financial stake in medical care, provides treatment for the mentally ill and the mentally defective in its various institutions.

The last group concerned is the Department of Public Health, which, almost from its inception has had a considerable stake in the problem of medical care. The first tuberculosis and cancer hospitals to be maintained at state expense were started in Massachusetts. Hospitalization of tuberculous patients is recognized as an integral part of a tuberculosis-control program. Immediate care is essential. If "red tape" holds up the hospitalization of a patient with tuberculosis, the chances of its spread among contacts is increased, and the likelihood of recovery is materially reduced. It is a well known fact that 85 per cent of tuberculosis cases can be arrested if treated in time. A major problem in the care of tuberculous wage earners is that frequently no provision is made to assure an adequate standard of living for their families. Steps are now being taken, however, to correct this deficiency.

State sanatoriums for the treatment of cancer patients are provided at Pondville and Westfield. The Department of Public Health also maintains twenty co-operative cancer clinics, at which the physicians give their services without compensation. These are essentially diagnostic clinics, since no operations are performed and no extensive radiotherapy is given. As in cases of tuberculosis and other communicable diseases, immediate care is vital. Experience has shown that the disease can

*Commissioner, Massachusetts Department of Public Health

Health agencies is done outside the official governmental agencies."

In planning for the future the voluntary health agency must discover for itself how it can advance public health. Thus, such an organization has a definite responsibility to assist in making community surveys of existing institutions and of other facilities for the improvement of the health of the people. In promoting its own activities and functions an agency must be cognizant of the work of other agencies to avoid duplication and overlapping. Moreover, it is essential that all voluntary health agencies begin to co-ordinate their programs so as to discharge their responsibilities more efficiently.

* * *

There are several immediate needs for public-health programs in Massachusetts. The first of these is the strengthening of the official agencies — namely, the state and local departments of health. A health department must be able to function free of political interference if it is to carry on its duties efficiently and on the basis of scientific knowledge. Thus, the health commissioners should be appointed by the Public Health Council rather than by the governor or the mayor of a city. They should be assured of some security of tenure and should not be subject to the turnovers that often follow a change in political regime. They should likewise be assured of reasonable compensation — one that would provide them with a standard of living equal to that of other leaders in medical practice in their communities. Their staffs should have similar protection and whenever possible they should be protected by Civil Service laws and should receive higher compensation than that received at the present time by practically all health department employees in the Commonwealth. As a matter of fact, in many health departments, there is a dearth of physicians and other professional personnel because of the comparatively low salaries paid these employees. It is therefore necessary that the Massachusetts Medical Society and other professional groups lend their support to the common effort of raising salaries for health-department employees in the Commonwealth. The professional salaries of the Massachusetts Department of Public Health personnel, which were set back in the 1920's, have not been changed, except for wartime increases. If state and local health departments are not able to obtain and to hold well trained personnel, the quality of public-health work will greatly depreciate, and this will enhance the politicians' opportunities to dispense jobs and federal grants not on merit but on any opportunity to favor his chances of election.

Local health departments must obtain adequately paid full-time personnel who do not engage in private practice and must form into town unions. They are to make available, to the citizens, the benefits of the latest developments in public

health. This calls for the unification of boards of health into a common board that would employ a full-time, specially trained public-health physician with an adequate staff of full-time professional assistants. The time is past when public-health administration can be considered a part-time activity or a field to which physicians who have conducted a full-time general practice can retire on reaching old age. To make possible the formation of town unions on a permanent basis legislation at first permissive and later compulsory may be necessary. This should provide for a state subsidy, to be made available to town unions for the operation of such health departments. This is the procedure that is already effectively carried on in many states.

Voluntary health agencies should support the official health departments not only in the obtaining of more adequate funds but also in the passage of proper legislation and in the strengthening of the departments that are sorely in need of adequate personnel and facilities. In the past, voluntary health agencies, by passive acquiescence rather than by active support, have often gone along with health departments and have not assumed their proper share of the responsibility.

Doctors, nurses, other professional workers, lawyers, bankers, civic leaders and representatives of all groups interested in health should band together and form community health councils. These councils not only should survey their communities to determine the facilities that are available for health and medical care but also should ascertain the needs of the communities and assist in formulating plans to meet such needs. The health councils should also co-ordinate the work of the various agencies, assist in the avoidance of duplication and help in the provision of more complete coverage most efficiently to expend the public funds collected through either taxation or voluntary contribution. Finally, community health councils, working with the assistance of the medical profession and health department, should develop continuous health education programs designed not only to keep the public informed on health matters but also to obtain public support for health programs.

By the strengthening of the official health agency by obtaining health departments free from political interference, by providing personnel adequately trained, secure in office and properly compensated, by co-ordinating the work of all the voluntary health agencies and by receiving the support of the public professional groups and civic leaders, public health in Massachusetts can attain the desired objective of all those interested in the health and welfare of the people — namely, optimal health. Only by this concerted and continued active support of all interested can this goal of optimal health be attained.

Similarly, the patient who is ill with a disease such as diabetes or cancer is primarily responsible for his own care. If he neglects his own health, however, either wilfully or because of lack of means, and becomes a burden on the community in that he is no longer self-supporting and his dependents are potential welfare charges, the health of the patient becomes the concern of the community. It assumes the responsibility for his care, so that he will not remain a continued liability but will again become an asset — independent, self-supporting and contributing to the public welfare.

Under the Constitution of the United States, the responsibility for the health and welfare of the people rests officially with the state and not with the federal government. The state may delegate this responsibility to its political subdivisions. In Massachusetts, the responsibility has been delegated to the state and local boards of health and of public welfare. Although there is an excellent health department on the state level, health departments have failed to provide the people with adequate health services on the local level. The provision of adequate health service, which is now a primary responsibility of health departments, can be attained only through the organization of permanent town unions. Each union should include about 30,000 people to provide for the employment of full-time, trained health workers. Since a minimum of approximately \$2.00 per capita is required for efficient health administration, a subsidy must be made available to these health departments from the state government. The local health department should be administered by a full-time physician not engaged in private practice. He should be advised by a board of health that has no executive authority. School health programs should be an integral part of the health department's function and closely co-ordinated with the other health activities.

* * *

The voluntary agency has a vital role in community health organization. Often, in our complex civilization, the official agency does not furnish all the facilities necessary to render complete and adequate care of the needy. The voluntary health agency can and should assume some of the burden by providing for the care of such groups of patients as are not included under the functions of the official agencies and by disseminating knowledge and promoting programs that increase the community's assets for the attainment of optimal health.

The voluntary health movement in the United States began about sixty years ago with the formation of the Pennsylvania Society for the Prevention of Tuberculosis. At that time this was an extraordinarily far-sighted step — one that was so far in advance of the times that it was not duplicated in other states for over ten years. A second state society was organized in Ohio in 1901, and a third in New York in 1902. The National Tuberculosis

Association was formed in 1904 and included twenty-three state and local organizations. These have increased to such an extent that at the present time there are over three thousand chapters in the United States. The most striking fact is the marked unevenness of the voluntary movement. There are over twenty thousand voluntary health agencies — some excellent, but others inadequate. I think it developed spontaneously to meet new recognized needs in a variety of neglected fields. The movement has lacked over-all direction and planning. The time is ripe for stocktaking and for developing sounder programs. Many of the present activities of volunteer societies should properly be absorbed by the official health departments, which, after all, are the responsible health agencies. There is therefore a need for increasing the co-ordination of effort on national, state and local levels. In fact, some authorities have advocated the unification of one strong organization of all the related health promoting voluntary agencies in a city or in a state with appropriate emphasis on the various aspects of a unified health program. Such authorities as Gunn and Platt¹ recommend "the pooling of the present separate competitive and confusing appeals of the voluntary national health agencies into a unified nationwide campaign effective on the local, state and national levels, along the lines already proved to be acceptable to the American people through the National War Fund in conjunction with the community chests."

On the other hand, certain groups are interested in promoting a compulsory health program administered by the federal government that would, to a large extent, sound the death knell of many of the voluntary health agencies. Even if the eventual taking over of all the technical services for public health by official agencies could be visualized, four important functions of the voluntary public health agencies would remain.

In the first place they would remain the guardian and watchdog of the official health departments. Voluntary organizations of alert and informed citizens, sensitive to the community's need in public health, can serve at all times to defend, strengthen, criticize, support and assist the official agency as servant of the public. Such organizations would always take an active interest in promoting health legislation in all levels of government. They are needed, especially if national in scope, to stimulate and finance research. Finally, they have a continuing educational function. They can develop machinery for supplementing official health and educational organizations and can augment the efforts of professional groups to popularize scientific knowledge bearing on health.

Voluntary health agencies are here to stay. A. Mustard² stated in a recent publication, "It requires only casual study of the situation to learn that a great deal of work important in maintaining public

penicillin an acid substance. The explanation was that the ionized forms of the basic drugs (streptomycin) compete with the hydrogen ions, and those of the acid drugs (penicillin) compete with hydroxyl ions, for position on the cell surface. Since tissue damage is accompanied by an increase in the local acidity, a concentration of a basic drug, such as streptomycin, that is effective in blood may be inadequate to destroy bacteria in local lesions.

The importance of alkalization of the urine during streptomycin therapy is brought out in a recent report by Kane and Foley¹¹ presenting the results of treatment in 38 cases of pyelonephritis and 2 cases of cystitis due to gram-negative bacilli. Most of the patients had previously been treated with sulfonamides, mandelic acid and penicillin. The duration of the infection in each case had varied from weeks to years. Seventy-five per cent of patients were cured, and 10 per cent showed improvement. It is noteworthy that several of the cured patients had small renal calculi, and others had moderate structural deformities. The failure in 15 per cent could be attributed in each case to the fact either that marked structural deformity was present or that the concentration of streptomycin necessary to inhibit the growth of the infecting organism was higher than could be obtained in the urine with the dosage employed. The authors attribute the more favorable results obtained in their series, as compared with those of others, to the fact that the urine in each case was rendered alkaline during therapy.

Certain toxic reactions may occur during treatment with streptomycin. These are chiefly sensitization reactions with skin eruptions and fever, vertigo and tinnitus.⁶ If a skin rash appears, it is advisable to stop streptomycin or continue treatment with care. In patients on prolonged courses of streptomycin, vertigo has been the most troublesome symptom, but many patients apparently overcome the subjective symptoms in spite of continued treatment. Tinnitus is considered a warning signal to decrease the dosage.

Although the streptomycin therapy of certain pyogenic infections of the urinary tract has been given at least a moderate trial and appears to be effective in many cases, particularly those due to gram-negative bacilli, its usefulness in renal tuberculosis is less clearly defined. This is because it soon became evident that long courses of treatment were necessary and supplies of streptomycin were limited. There is some evidence, however, that streptomycin is helpful in this disease. The results in 12 patients with genitourinary tuberculosis treated with streptomycin at the Mayo Clinic were sufficiently encouraging to make further trial interesting.¹² Although the patients were probably not treated for sufficiently long periods, a temporary beneficial effect was obtained in a reasonable number of cases. Pyuria was decreased, vesical symptoms were improved in some and the number of

tubercle bacilli in the urine was said to have decreased. Bladder ulcerations healed in a case of renal infection treated over a long period and reported by Allea.¹³ There are no reports of streptomycin therapy in cases of early renal tuberculosis.

TESTICULAR NEOPLASMS

Hormonal tests for the diagnosis and prognosis of testicular neoplasms were in general use ten or twelve years ago. Indeed, a classification of these tumors was advocated at one time on the basis of quantitative determinations of the gonadotropic hormone in the urine.^{14, 15} These tests have been largely abandoned because of inconsistent results. Embryonal carcinomas, teratomas and seminomas—all of them malignant—frequently gave negative tests before operation. It soon became evident, moreover, that the tests did not always provide an accurate index of the subsequent course of the disease. Many patients with advanced metastatic lesions gave negative tests.

Brewer¹⁶ recently reported 2 cases of primary testicular neoplasms. The histologic diagnosis in one was teratoma, and in the other, seminoma. The metastases in both cases, however, were chorioepitheliomas. When each patient was first seen tests for chorionic gonadotropin in the urine (Friedman and Aschheim-Zondek tests) were positive. It was believed that although chorionic tissue had not been demonstrated histologically in the primary tumor, it must have been present, since chorionic gonadotropin was present in the urine and the metastases were chorioepitheliomas. Small areas of chorioepithelioma may have been present in the primary tumor but not detected on microscopic examination because the entire tumor was not examined or because it may be difficult to differentiate chorionic tissue from the varied tissues composing a testicular neoplasm.

That two distinct types of gonadotropin reactions occur in tests with testicular tumors is pointed out by Brewer. These reactions represent two different gonadotropic hormones. One is the chorionic type of gonadotropin, identical with that formed in the urine of pregnant women, it produces luteinization in the ovarian follicles of test animals. The second type of gonadotropin is the castrate type elaborated in the pituitary gland. This hormone is present in the urine of male or female castrates, in women past the menopause and in elderly men. It produces follicle growth but not luteinization in the ovaries of test animals.

It is necessary to distinguish between these two reactions when testing for tumors of the testis, and failure to do so has caused confusion in the correlation of the test and the type of tumor. Brewer considers the presence of chorionic gonadotropin in the urine to indicate the presence of a biologically active tissue, whereas the presence of castrate type of gonadotropin means merely a reduction or cessation

MEDICAL PROGRESS

UROLOGY

FLETCHER H COLBY, M D *

BOSTON

THE following is a review of recent studies on the use of streptomycin in urologic infections, testicular neoplasms, retroperitoneal tumors and necrotizing renal papillitis

STREPTOMYCIN

Considerable progress has been made in recent years in ability to control infections of the urinary tract. Mandelic acid, the sulfonamides and penicillin have played a role in the problem, and during the past year another preparation has become available for this purpose. In 1944 Schatz, Bugie and Waksman¹ first described the isolation of a new antibiotic agent that they named "streptomycin." Animal experiments demonstrated the low toxicity of this agent and its effectiveness against infections due to gram-negative bacilli.²⁻⁵ Since any one of these preparations is chiefly effective against certain groups of bacteria, or even strains of bacteria, the value of the identification of the infecting organism has become increasingly clear. The sensitivity of the bacteria to the therapeutic agent has also become an important consideration.

The method of preparation and directions for the administration of streptomycin are given in a report of the Committee on Chemotherapeutics and Other Agents of the National Research Council.⁶ Streptomycin is available as the sulfate salt or the hydrochloride salt. Both salts are readily dissolved in distilled water or isotonic sodium chloride solution. Concentrations of 100 to 175 mg of streptomycin per cubic centimeter of solution are prepared for intramuscular injection. Enough solution should be used so that the preparation is clear and free of undissolved particles. The total volume should be as small as possible. The expiration date of vials of streptomycin is eighteen months after release. The drug should be kept in the refrigerator. Intramuscular injection is the method generally employed for urinary-tract infections. Maximum serum levels of streptomycin are reached within one to three hours after intramuscular injection, and additive effects are obtained by a repetition of the dose every three or four hours. Most of the streptomycin is excreted from the blood into the urine by the kidneys.

Four hundred and nine cases of infection of the urinary tract are included in the report by the Committee on Chemotherapeutics and Other Agents

All cases were resistant to the sulfonamides, many varieties of bacteria were represented. Many of the patients were given daily intramuscular injections of solutions containing 1 or 2 gm of streptomycin for five to seven days, with an average total dose of 7.5 to 10 gm. Many infections were of longstanding. The over-all recovery rate in this series was 42 per cent. It was concluded that it was difficult to assess the relative merits of streptomycin in this group of infections, but many of the patients were improved, without recurrences. Mixed infections did not respond so well as those due to a single organism. A rapid development of resistance by bacteria to streptomycin was observed, and was thought that this accounted for many cases of failure to sterilize the urine. The favorable effect of streptomycin on infections due to *Proteus* species in this series should be noted.

A rapid increase in resistance to streptomycin organisms infecting the urinary tract appears to be a major problem, and this fact merits careful consideration in the future treatment of patients with such infections. Sensitivity tests in vitro seem to be a reasonable guide to treatment. The rapidity with which organisms can acquire resistance to streptomycin is emphasized in a report from the Boston City Hospital by Finland et al.⁷ and by others.⁸ The former showed that in 8 carefully observed cases of urinary-tract infection a considerable degree of resistance to streptomycin was acquired by the infecting organisms within a short time. Repeat tests of organisms isolated before treatment showed them to be sensitive in vitro, whereas those obtained after treatment were highly resistant and the patients failed to respond to apparently adequate doses of streptomycin. It has been stated that dosage should be guided by the sensitivity of the organisms and that, when possible, an adequate concentration of streptomycin should be maintained in the blood and tissues to inhibit the growth of organisms.⁹ It was thought that in this way the resistance to streptomycin could be reduced. For urinary-tract infections a daily dose of 1 to 3 gm for five to ten days was recommended.⁶

Streptomycin is most effective in an alkaline medium. This fact was observed by Schatz, Bugie and Waksman¹ and confirmed by Abraham and Duthie.¹⁰ Differences as great as tenfold were encountered between activities measured at reaction of pH 6.0 and pH 8.0. The reverse was true of

*Chief Urological Service, Massachusetts General Hospital

penicillin an acid substance. The explanation was that the ionized forms of the basic drugs (streptomycin) compete with the hydrogen ions, and those of the acid drugs (penicillin) compete with hydroxyl ions, for position on the cell surface. Since tissue damage is accompanied by an increase in the local acidity, a concentration of a basic drug, such as streptomycin, that is effective in blood may be inadequate to destroy bacteria in local lesions.

The importance of alkalization of the urine during streptomycin therapy is brought out in a recent report by Kane and Foley¹¹ presenting the results of treatment in 38 cases of pyelonephritis and 2 cases of cystitis due to gram-negative bacilli. Most of the patients had previously been treated with sulfonamides, mandelic acid and penicillin. The duration of the infection in each case had varied from weeks to years. Seventy-five per cent of patients were cured, and 10 per cent showed improvement. It is noteworthy that several of the cured patients had small renal calculi, and others had moderate structural deformities. The failure in 15 per cent could be attributed in each case to the fact either that marked structural deformity was present or that the concentration of streptomycin necessary to inhibit the growth of the infecting organism was higher than could be obtained in the urine with the dosage employed. The authors attribute the more favorable results obtained in their series, as compared with those of others, to the fact that the urine in each case was rendered alkaline during therapy.

Certain toxic reactions may occur during treatment with streptomycin. These are chiefly sensitization reactions with skin eruptions and fever, vertigo and tinnitus.⁶ If a skin rash appears, it is advisable to stop streptomycin or continue treatment with care. In patients on prolonged courses of streptomycin, vertigo has been the most troublesome symptom, but many patients apparently overcome the subjective symptoms in spite of continued treatment. Tinnitus is considered a warning signal to decrease the dosage.

Although the streptomycin therapy of certain pyogenic infections of the urinary tract has been given at least a moderate trial and appears to be effective in many cases, particularly those due to gram-negative bacilli, its usefulness in renal tuberculosis is less clearly defined. This is because it soon became evident that long courses of treatment were necessary and supplies of streptomycin were limited. There is some evidence, however, that streptomycin is helpful in this disease. The results in 12 patients with genitourinary tuberculosis treated with streptomycin at the Mayo Clinic were sufficiently encouraging to make further trial interesting.¹² Although the patients were probably not treated for sufficiently long periods, a temporary beneficial effect was obtained in a reasonable number of cases. Pyuria was decreased, vesical symptoms were improved in some and the number of

tubercle bacilli in the urine was said to have decreased. Bladder ulcerations healed in a case of renal infection treated over a long period and reported by Alvea.¹³ There are no reports of streptomycin therapy in cases of early renal tuberculosis.

TESTICULAR NEOPLASMS

Hormonal tests for the diagnosis and prognosis of testicular neoplasms were in general use ten or twelve years ago. Indeed, a classification of these tumors was advocated at one time on the basis of quantitative determinations of the gonadotropic hormone in the urine.^{14, 15} These tests have been largely abandoned because of inconsistent results. Embryonal carcinomas, teratomas and seminomas—all of them malignant—frequently gave negative tests before operation. It soon became evident, moreover, that the tests did not always provide an accurate index of the subsequent course of the disease. Many patients with advanced metastatic lesions gave negative tests.

Brewer¹⁶ recently reported 2 cases of primary testicular neoplasms. The histologic diagnosis in one was teratoma, and in the other, seminoma. The metastases in both cases, however, were chorioepitheliomas. When each patient was first seen tests for chorionic gonadotropin in the urine (Friedman and Aschheim-Zondek tests) were positive. It was believed that although chorionic tissue had not been demonstrated histologically in the primary tumor, it must have been present, since chorionic gonadotropin was present in the urine and the metastases were chorioepitheliomas. Small areas of chorioepithelioma may have been present in the primary tumor but not detected on microscopic examination because the entire tumor was not examined or because it may be difficult to differentiate chorionic tissue from the varied tissues composing a testicular neoplasm.

That two distinct types of gonadotropin reactions occur in tests with testicular tumors is pointed out by Brewer. These reactions represent two different gonadotropic hormones. One is the chorionic type of gonadotropin, identical with that formed in the urine of pregnant women, it produces luteinization in the ovarian follicles of test animals. The second type of gonadotropin is the castrate type elaborated in the pituitary gland. This hormone is present in the urine of male or female castrates, in women past the menopause and in elderly men. It produces follicle growth but not luteinization in the ovaries of test animals.

It is necessary to distinguish between these two reactions when testing for tumors of the testis, and failure to do so has caused confusion in the correlation of the test and the type of tumor. Brewer considers the presence of chorionic gonadotropin in the urine to indicate the presence of a biologically active tissue, whereas the presence of castrate type of gonadotropin means merely a reduction or cessation

of testicular function. As applied to testicular tumors, then, the chorionic gonadotropin is the more important hormone, and its presence in the urine is detected by the usual tests of pregnancy.

The results of orchidectomy and external irradiation in 80 cases of malignant testicular neoplasm by Nesbit and Lynn¹⁷ give a survival rate of 24 per cent. The patients were followed for a minimum of four years. It is pointed out that an occasional patient of this sort with metastases has survived long enough to be fairly regarded as cured. Two patients with proved metastases have lived for eleven and twelve years following treatment with no evidence of recurrence. Four patients lived from four to six years and then died of the disease, so that any study based on a four-year follow-up is considered subject to approximately a 10 per cent error. Only about a third of the cases reported by Nesbit and Lynn showed a significant elevation in prolan level. Removal of the tumor and postoperative — not preoperative — irradiation are favored by the authors.

A surprisingly high incidence of testicular tumors was found in the armed forces. Vermooten¹⁸ attributed this to the easier access to medical advice, frequent examinations and the rigors of training. He explained the low incidence of metastases by the earlier diagnosis made possible because of these facts. Others, however, reported a high incidence of metastasis (24 per cent) among soldiers when first seen with testicular neoplasms and discouraging results after treatment.¹⁹ No correlation was demonstrable between the results and the duration of the disease before treatment or the type of tumor.

From 1940 to 1946 the Army Institute of Pathology collected 922 cases of tumor of the testis from Army patients.²⁰ Over 96 per cent of these neoplasms fell into the following classifications: seminoma (germinoma), 35 per cent, embryonal carcinoma, 19 per cent, and chorioepithelioma, 0.4 per cent, teratoma, 7 per cent, and teratocarcinoma, 35 per cent. Clinically as well as histologically the seminomas were less malignant than the embryonal carcinomas, and the authors expressed the opinion that these tumors differ not only in fundamental cell type but also in biologic behavior and prognosis.

Fully differentiated chorioepitheliomatous tissue was present in about 6 per cent of embryonal carcinomas, and the hemorrhagic necrosis and vascular invasion characteristic of chorioepitheliomas were frequently seen in the embryonal carcinomas. Pure primary chorioepitheliomas accounted for less than 0.4 per cent of the tumors. The fact that chorionic gonadotropin is often present in the urine of patients with so-called "embryonal adenocarcinoma" is considered to provide physiologic substantiation for the morphologic observation that many embryonal carcinomas are trophoblastic tumors. The new term "teratocarcinoma" is proposed to include the large group of pleomorphic tumors in which both differen-

tiated teratoid structures and histologically malignant elements are present.

An interesting feature of this group of tumors was that the death rate and incidence of metastasis were practically the same for the adult teratomas and the teratocarcinomas, supposedly because a teratocarcinoma matured into an adult teratoma after malignant embryonal cells had already been disseminated to other parts of the body. A study of the histologic components of the primary tumor and the metastases showed that 90 per cent of the embryonal carcinomas metastasized as embryonal carcinomas or chorioepitheliomas and that 40 per cent of the metastases of teratocarcinomas were embryonal carcinomas or chorioepitheliomas. It therefore appears obvious that any of these tumors may display chorioepitheliomatous tissue in their secondary deposits. Whereas only 0.4 per cent of these tumors were pure chorioepitheliomas, 27 per cent of all the metastases in cases that terminated fatally contained chorioepithelial elements. This excellent report deserves the attention of all who are interested in tumors of the testis.

In a study of testicular neoplasms in dogs Huggins and Pazos²¹ found that atrophy of the prostate was present in all tumors except the interstitial-cell variety, in which the prostate was normal or enlarged. The authors present evidence that the interstitial-cell tumors arose from the Leydig cells and that the tubular adenomas originated from the cells of Sertoli. They also confirmed previous observations that seminomas arose from the germinal epithelium.

Most of the recent reports on tumors of the testis emphasize what has long been regarded as an important feature in their management. This is ligation of the spermatic cord high in the inguinal canal and removal of the affected scrotal contents through this incision without opening the tunica vaginalis. This procedure lessens the likelihood of local recurrence from tumor-cell implantation. In a recent case of a highly malignant testicular tumor in our own experience, the hydrocele fluid associated with the neoplasm was found to contain many tumor cells in the stained smear.

RETROPERITONEAL TUMORS

Tumors that arise independently in the retroperitoneal tissues are not frequent but are of considerable interest. This group of neoplasms concerns both the general surgeon and the urologist, since the outstanding sign is often an unexplained abdominal mass, and the close relation of the mass to the kidneys and ureters is apt to deform or displace these organs. Past references concerning primary retroperitoneal tumors have not been complete. All the available information about these tumors is presented by Donnelly,²² with a report of 95 cases observed during the past twenty years at the University of Iowa Hospitals.

The retroperitoneal space is described as between the lumbar and iliac regions and between the peritoneum and the posterior parietal walls of the abdominal cavity. The tumors originate within this space behind the posterior peritoneum. They may take origin from the urogenital ridge fatty or connective tissue, lymphatic vessels or sympathetic nervous tissue. As they enlarge, they displace the abdominal viscera and may involve the mesentery of the large or small bowel. The tumors may be benign or malignant and occur at any age. The wide diversity of cell types of retroperitoneal tumors was once explained on the basis that they arose from remnants of the urogenital apparatus.²³

Primary retroperitoneal neoplasms have varied considerably histologically. Sarcomas were regarded as the most frequent of the malignant tumors and lipomas as the most frequent of the benign types. The nonmalignant tumors are said to be potentially malignant and prone to recur. Even the lipomas when they occur retroperitoneally have a tendency to undergo malignant change with recurrence and death. This tendency to recur is also true of other usually benign tumors when retroperitoneal—namely fibromas and leiomyomas. The explanations given for this fact are that small outgrowths of these tumors are overlooked and not removed at operation and that the tumors contain sarcomatous elements not readily identified histologically.

Retroperitoneal cysts represent a type of these tumors. They have been classified as cysts of urogenital origin, teratomatous cysts and lymphatic, traumatic and parasitic cysts. They are most frequent in women from fifteen to twenty-five years of age and usually occur on the left side. The preoperative diagnosis is apt to be ovarian cyst.²⁴

Of the 95 cases of primary retroperitoneal tumors in Donnelly's²⁵ series 82 were classified as malignant, and 13 as benign. Sarcoma, fibrosarcoma and undifferentiated neoplasms, such as embryoma and adenocarcinoma, were the most frequent accounting for 81 per cent of the malignant tumors. Epithelial cysts were the most frequent benign tumors.

Gastrointestinal symptoms predominated in the patients with retroperitoneal neoplasms. Indefinite abdominal pain in the lower abdomen, nausea, constipation and anorexia were the usual complaints. Some patients noted the presence of an abdominal mass. As the mass increases in size, the symptoms are those resulting from pressure on adjacent structures. Symptoms had averaged over nine months before these patients sought treatment.

Patients with retroperitoneal tumors usually presented diagnostic problems. Gastrointestinal x-ray films and retrograde pyelograms assisted in the making of a correct diagnosis before operation. When these steps had been omitted the preoperative diagnosis had usually been ovarian tumor in the women and cancer of the gastrointestinal tract in men.

The treatment of these tumors is exploratory abdominal operation with removal of the tumor mass if possible. Eighty-two of the patients in this series were operated on. Forty-eight, or 65 per cent, were found unsuitable for surgical removal. Twenty-eight patients received deep x-ray treatment, and 77 per cent of the tumors were considered radio-sensitive. Best results were obtained when complete surgical excision of the tumor was possible. An operative mortality of 20 per cent indicates the hazard of surgery in patients with primary retroperitoneal tumors.

NECROTIZING RENAL PAPILLITIS

An interesting and usually fatal type of suppurative pyelonephritis that is frequently but not always, associated with diabetes is described by Robbins, Mallory and Kinney.²⁶ The pathologic characteristics of this condition are abscesses in the renal pyramids with sufficient extension to cause necrosis of the terminal portion and suppuration and gangrene of the renal papillae. In most of the cases death was directly attributable to a necrotizing papillitis. Miscellaneous organisms are involved. Clinically this lesion should be suspected in severe acute urinary-tract infections in diabetic and non-diabetic patients with urinary obstruction, particularly in the presence of oliguria and a rising non-protein nitrogen. In the later stages of the disease pyelographic changes may be present.

CASE 33171

PRESENTATION OF CASE

A sixty-six-year-old Canadian housewife was admitted to the hospital for the fourth time because of recurrent pain in the right upper quadrant.

Two years before admission occasional attacks of sharp pain in the right upper quadrant had begun, sometimes originating at about the anterior axillary line and radiating to the epigastrium and substernal region. At other times the pain originated in the epigastrium and radiated to the right, along the lower costal margin to the infrascapular region. Radiation was also described as at times going into the right shoulder. These attacks recurred at monthly intervals and had become more frequent in the past year, sometimes only a few days apart. A year before admission a physician told the patient that she had gall-bladder trouble and started her on bile salts and a fat-free diet. She had been forced to call her physician frequently for the pains in the right upper quadrant, which were relieved by pills taken by mouth. At times these attacks of pain were associated with chills. During the attacks she became nauseated and sometimes vomited. She had considerable gas and had been constipated about a year, obtaining relief with mineral oil. About a month before admission her daughter noted that the patient had become yellow, but this had not increased in intensity and the patient thought that it had decreased. The stools had been clay colored but later were brown. She had been losing weight despite a fair appetite, falling from 220 pounds in 1936 to about 150 pounds at the time of admission.

The first admission to the hospital had been thirteen years previously because of a tumor in the right breast of five months' duration. This had proved to be carcinoma, and a radical mastectomy had been performed. The axillary lymph nodes

were not involved. The patient did well until ten years later, when she again complained of tenderness and an indefinite tumor in the upper outer quadrant of the left breast, suggesting cystic disease. She was readmitted about eight months later, after considerable urging, and a left radical mastectomy was performed for another breast carcinoma. No involvement was seen in the axillary lymph nodes. About a year and a half after the second operation a firm oval nodule developed on the left that was slightly tender and adherent to the skin but not to the chest wall. This was excised and diagnosed as recurrent carcinoma. The patient then did well until six years before the present admission, when she noticed a small lump on the tip of the tongue. This increased slightly in size until all the teeth were extracted, when the lump began to decrease and subsided to the point where it was not necessary for her to return. Letters stated that she was well. A year prior to admission she had pneumonia and was confined to bed for three weeks at home and treated with sulfonamides and penicillin. She also stated that for the past twelve years she had had high blood pressure. Otherwise, she had no cardiac symptoms other than ankle edema in the evening, which had been present for about thirty years. She had also noted occasional palpitation and moderate exertional dyspnea.

Physical examination revealed a well developed, well nourished, slightly jaundiced woman lying quietly in bed in no acute discomfort. There was no evidence of recurrence in either of the mastectomy scars, and the chest was clear to percussion and auscultation. The heart did not appear to be notably enlarged. A Grade II, harsh systolic murmur was heard in both the apical and the aortic areas and transmitted to the neck, but the aortic second sound was not obliterated. There was no thrill. The abdomen was soft and obese, with moderate tenderness to pressure in the right upper quadrant in the midclavicular line, but no spasm and no masses. The liver was not palpated. There were minimal osteoarthritic changes of the distal phalanges of both hands. Over the ninth and tenth dorsal vertebrae there was a subcutaneous, freely movable, nontender mass, measuring 3 by 3 cm., that was apparently a collection of adipose tissue.

The temperature, pulse and respirations were normal. The blood pressure was 220 systolic, 95 diastolic.

Examination of the blood disclosed a hemoglobin of 104 per cent and a white-cell count of 6250. The urine gave a ++ test for albumin, with a questionably positive test for bile. The stools were pale brown and guaiac positive. An electrocardiogram was described as showing sinus arrhythmia, with auricular premature beats, a rate of 46, a PR interval of 0.16 second, a QRS of 0.06 second, normal voltage, a tendency to left-axis deviation, a notched S₂, upright T waves in Leads 1, 2 and 3 and in Leads CF, CF₁, and CF₂, and slight sagging of the ST segment in Lead CF₃. X-ray studies of the chest and abdomen revealed no notable abnormality, no calculi were recognized in the abdomen. A bromsulfalein test revealed 28 per cent retention of the dye. The blood phosphorus was 3.7 mg, the non-protein nitrogen 28 mg, the cholesterol 294 mg and the cholesterol esters 130 mg per 100 cc, and the alkaline phosphatase 20.9 Bodansky units. The prothrombin time was normal. A van den Bergh test was 1.6 mg per 100 cc direct and 2.2 mg indirect. The total protein was 7.46 gm per 100 cc, with an albumin-globulin ratio of 1:3. A cephalin-flocculation test was negative in twenty-four hours and ++ in forty-eight hours.

On the fourth hospital day a peritoneoscopy was negative. Two days later intravenous pyelograms and a barium enema were essentially negative. The liver was noted to be somewhat enlarged, slightly depressing the hepatic flexure. On the next day a gastrointestinal series revealed a 5-cm, sharply demarcated, nodular tumor mass arising from the lateral aspect to the body of the stomach, a repeat bromsulfalein test revealed 20 per cent retention of the dye. On the twelfth hospital day a gastroscopy was performed, revealing a slightly atrophic antrum with a tightly closed, pale, normal pylorus. On the greater curvature, just proximal to the angulus, there was a nodular, polypoid, mulberry reddish-purple, easily bleeding mass about 4 by 4 cm in diameter and somewhat spherical in shape. It seemed to be wholly confined to the greater curvature. Toward the anterior wall the mucosa was pale and numerous blood vessels were easily visible.

Two weeks after admission cholecystectomy was performed with exploration of the common duct. At operation multiple small calculi, measuring up to 8 mm in diameter, were found in a chronically thickened gall bladder. The common duct measured 10 mm in diameter and was explored without the finding of a stone. Two masses in the head of the pancreas were biopsied and frozen section revealed chronic pancreatitis. The body and tail of the pancreas were irregular and nodular, the individual nodules measuring up to 20 mm in diameter. None of these were thought by the surgeon to be typical of carcinoma. The gastric lesion measured roughly 5 cm in diameter and was apparently attached to the greater curvature half way between the angulus

and the cardiac end of the stomach. There were three small, tiny, lymphatic nodules and subserous lacteals in the greater curvature over the base of the tumor, but the lesion was thought to be resectable from the abdomen. On the day following cholecystectomy a bilateral prophylactic superficial-vein interruption was done, and about a month after admission a subtotal gastrectomy was performed.

DIFFERENTIAL DIAGNOSIS

DR CLAUDE E. WELCH: The first part of this history is a fairly definite story of gall-bladder disease probably on the basis of common-duct stone because of the repeated attacks and the fact that the common-duct obstruction had been intermittent in type, as evidenced by the stools. The only feature that we cannot explain well on the basis of gall-bladder disease is the rather marked loss in weight.

Dr Fav assures me that these electrocardiograms are essentially normal.

This patient had some type of jaundice. The evidence points definitely toward obstruction of some type, as indicated by the high alkaline phosphatase. There is also evidence of a certain amount of liver damage as shown by retention of bromsulfalein, although it was not marked because of the normal prothrombin time. There were moderately elevated cholesterol and cholesterol ester levels, whereas the van den Bergh reaction showed evidence of slight jaundice. The flocculation tests were equivocal. All the heart studies, I should say, indicate that the patient was a good preoperative risk — almost anyone who walks around is a good risk, I understand. The x-ray film showed something that was not expected. May we see the film?

DR RICHARD SCHATZKI: Do you want to see the stomach film?

DR WELCH: I want to spend more time on that than on anything else.

DR SCHATZKI: We have one film not a spot film, on which the mass that was described can be seen.

DR WELCH: Can you tell about the margins of the tumor?

DR SCHATZKI: From this film I assume that it was a polypoid mass in the lumen of the stomach.

DR WELCH: You do not wish to say whether this area on the other side is normal?

DR SCHATZKI: In this film I think that I can see the upper edge of the mass. I cannot see the lower edge which must be hidden by barium. On the plain film of the abdomen the lower edge of the liver appears rather low laterally but the liver edge is quite sloped and I do not dare to guess its size. I suspect, however, that the liver is a little enlarged but with the liver edge so sloped as this a moderately low liver does not mean much.

This is the intravenous pyelogram. The dye is not well concentrated, but I cannot see anything wrong with the kidneys.

The chest film shows the area of the missing breast on the left side, and there is no evidence of metastases.

DR WELCH: The surgeon was faced with quite a problem—a known tumor of the stomach and a pathologic process in the biliary tract. Which should be attacked first, or should he be brave or foolhardy and attempt to do both at once? I assume that the wiser choice was taken in this case, because the patient had a low liver function and it was better to have the biliary tract functioning well before attempting gastric resection. The operation was probably done with the view of relieving the jaundice.

The empty common duct probably surprised the surgeon, and he undoubtedly explained it by saying that stones had passed through the common duct.

Many years ago, when Dr. Richard C. Cabot conducted these conferences, he put all his eggs in one basket and stated one diagnosis, which he made to cover all the findings. In these days, perhaps because the general incidence of older patients is so much higher, we consider ourselves lucky if we have such a thing as an uncomplicated carcinoma of the stomach. Obviously, in this patient it is impossible to make a single diagnosis to cover all the lesions. In the first place, the main problem that arises is that of the diagnosis of the stomach tumor, which may have been a primary tumor in the stomach, a recurrence of the carcinoma of the breast or a carcinoma of the pancreas that had been overlooked and had metastasized to the liver and to the stomach. The x-ray studies are helpful in that regard, because they rule out, for all practical purposes, any metastatic lesions. For an isolated metastasis to the stomach from carcinoma of the breast to show up six years after the last metastatic nodule had been observed would be queer indeed. Metastasis to the stomach from carcinoma of the pancreas is almost unknown, and a metastatic lesion of the stomach from either source that presented this x-ray picture would be impossible. We are therefore left with a discussion of the primary tumors of the stomach that can produce such an x-ray picture and give these findings by gastroscopy.

Before I saw this x-ray film I could not make up my mind regarding the exact type of tumor. Quite a list crossed my mind, such as fibrosarcoma, neurogenic sarcoma and leiomyosarcoma, all of which are frequent and produce spherical masses in the stomach, as well as an ectopic pancreas or lymphosarcoma. All these tumors were ruled out by the x-ray picture, which is not typical of any of them. We are restricted, practically speaking, to whether the lesion was a malignant polyp or a polypoid carcinoma. The gastroscopic picture does not help

us a great deal in this regard. I should like to know whether any induration was noted around the base of the tumor, but I assume that there was none, since it would have been mentioned.

So far as the question of a gastric polyp or gastric carcinoma is concerned, Drs. Benedict and Allen* looked up these lesions many years ago. They found that 40 per cent of the entire group were carcinoma. The diagnosis perhaps could have been aided by a smear of the gastric sediment to determine if any abnormal cells were found. As it is, I shall have to guess that, because the tumor was large, the stools contained occult blood and the patient had lost a fair amount of weight, we are dealing with a carcinoma rather than with a polyp of the stomach.

My diagnoses are carcinoma of the stomach, gallstones and chronic pancreatitis.

DR TRACY B. MALLORY: Dr. Robertson, will you give the opinion on the ward regarding the selection of procedures?

DR CHARLES W. ROBERTSON: Dr. Welch went through exactly the same reasoning we did on the ward. The patient was a hypertensive woman with known obstructive jaundice and a gastric lesion. The x-ray film that we have here is, I believe, one of the later films that were taken between the two operations. On the first film of the stomach we were impressed by the nearness of the lesion to the cardia of the stomach and the possibility of mucosal extension of the tumor to the esophagus, and for that reason we seriously considered exploration through the chest. That is why the statement was made at the first operation that the tumor was resectable abdominally. The findings at the first operation were exactly as the record described them—namely, a chronic pancreatitis and a chronically inflamed gall bladder, with evidence that the patient had probably been passing small calculi. The jaundice cleared up quickly following drainage of the common duct. The stomach was then resected abdominally, two and a half weeks later.

CLINICAL DIAGNOSIS

Gastric carcinoma?

DR WELCH'S DIAGNOSES

Carcinoma of stomach
Cholelithiasis
Chronic pancreatitis

ANATOMICAL DIAGNOSES

Multiple polypoid carcinomas of stomach, with metastasis
Chronic cholecystitis
Chronic pancreatitis

PATHOLOGICAL DISCUSSION

DR MALLORY: At the second operation a subtotal gastrectomy was done, and a large polypoid

*Benedict E. B. and Allen A. W. Adenomatous polypi of stomach. Surg. Gynec. & Obst. 58:79, 1934.

tumor with central ulceration was found. To one side of that and separated from it by a strip of apparently normal-looking mucosa was a second polypoid tumor. Whether this represented two separate malignant lesions of the stomach or whether one was an extension of the other, it is impossible to say. It is quite possible that there were two separate tumors. Both were malignant histologically and one or the other of them had led to a minute metastasis to a single lymph node, which we eventually found after sectioning a number of them.

DR WELCH: An excellent reason for delaying the operation until after the biliary tract had been explored is the fact that polypoid carcinoma is relatively slow to metastasize.

DR MALLORY: Dr Schatzki, have you any further comment?

DR SCHATZKI: So far as the tumors are concerned on the film, one can see only the upper edge of the larger lesion. The rest is merely barium.

CASE 33172

PRESENTATION OF CASE

A fifty-one-year-old housewife entered the hospital because of jaundice.

Three and a half months before admission the patient had noted the onset of anorexia and epigastric distention. Six weeks before entry generalized pruritus began. On two occasions the temperature was elevated to 99.2 and 99.4°F. Dark urine was noted a month before entry, and a week later definite jaundice appeared. With the onset of the jaundice the stools became light yellow. The patient believed that she had lost 10 to 15 pounds in the six months preceding admission. No unusual intolerance to fatty food had developed, but she had always avoided them because she thought that they caused hyperacidity. She denied using alcohol or drugs. Two months before admission and again a month later, she had visited a sister who was hospitalized with infectious hepatitis.

Except for a single attack of rheumatic fever in childhood, the past history was noncontributory.

On examination the patient was thin and fretful. The skin and scleras were yellow. Over the bridge of the nose there were several telangiectases. The lungs were normal. An early Grade II diastolic murmur was heard at the apex. The liver edge, which was palpated 4 cm below the ribs in the anterior axillary line and 8 cm below the xiphoid, was smooth, firm and nontender. The tip of the spleen was palpable on deep inspiration. The uterus was normal rounded and about the size of an orange.

The temperature was 98°F, the pulse 89, and the respirations 19. The blood pressure was 140 systolic, 80 diastolic.

Examination of the blood revealed a hemoglobin of 13.2 gm per 100 cc and a white-cell count of

11,000, with 72 per cent neutrophils. The urine was cloudy and orange. The specific gravity was 1.020, there was no albumin, sugar or bile, but urobilinogen was present in a dilution of 1:80, there were 6 epithelial cells per high-power field in the sediment. The stools were tan to light grayish tan. A guaiac test was + on two occasions, and negative on one. The total protein was 6.9 gm per 100 cc, with an albumin-globulin ratio of 1:4 and the cholesterol was 208 mg, the nonprotein nitrogen 21 mg, the vitamin A 70 mg, the carotenoid 40 mg, and the alkaline phosphatase 7.7 Bodansky units per 100 cc. The serum bilirubin was 4.2 mg per 100 cc direct and 5.6 mg indirect. The cephalin-flocculation test was negative after twenty-four hours and + after forty-eight hours. The prothrombin time was 13 seconds (control 15 seconds). A plain film of the abdomen was normal. There was no filling of the gall bladder during the Graham test.

In the hospital the patient continued to have slight itching, moderate jaundice and a normal temperature. On the third day the serum turbidity test* was 4.3 units at the end of thirty minutes and the thymol flocculation test was ++++ at forty-eight hours.

On the thirteenth day the phosphatase was 11.3 Bodansky units per 100 cc, the phosphorus 3.5 mg, the bilirubin 5.8 mg direct and 7.5 mg indirect. The prothrombin time was 19 seconds (control 16 seconds). Five milligrams of bromsulfalein per kilogram of body weight injected intravenously showed 30 per cent retention of the dye in forty-five minutes.

The liver remained about the same size. Subsequently the jaundice increased slightly, and the stools became definitely clay colored and were only slightly positive for bile. On the twenty-fifth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR ALLEN G. BRAILEY: This case illustrates a frequent and often puzzling problem—the cause of jaundice. Jaundice is the visible expression of hyperbilirubinemia, which in turn may be caused by increased blood destruction or by inability of the damaged liver to excrete the bile adequately. The first possibility—namely, that this patient had hemolytic jaundice—seems out of the question. In its favor are the absence of bile in the urine and some evidence of enlargement of the spleen, but the course of the disease was not that of acholuric jaundice. No familial history of this condition was obtained, and tests for spherocytosis and increased fragility of red cells were not done. Obviously, the service did not consider hemolytic jaundice, and I think that we should not do so either.

It is much less easy to dispose of the suggestion that the patient had some form of intrahepatic parenchymal disease. For example, the entire course

*Neefe J. R. Results of hepatic test in chronic hepatitis without jaundice: correlation with clinical course and liver biopsy findings. *Gastroenterology* 57:119, 1946.

is not inconsistent with infectious hepatitis. The onset was rather protracted, but such an onset certainly occurs. It is thrown in for good measure that her sister had been hospitalized with infectious hepatitis. This patient's illness, however, appears to have antedated exposure to her sister's infection. She had had jaundice for a total of at least six weeks, but that is not an unusual duration, nor is it unusual for the jaundice to be getting worse instead of better at the end of such an interval. It is reported that at the end of six weeks the stools became definitely clay colored, and this ought to mean, if she had hepatitis alone, that the liver cells were so severely damaged that they were no longer secreting bile. Opposed to such a notion is the rather remarkable lack of evidence of parenchymal damage. We are presented with an impressive array of liver-function tests but for the most part they were all within normal range—the total protein, the albumin-globulin ratio, the cholesterol, the cephalin flocculation, the vitamin A and the prothrombin time. The thymol-turbidity test gave a borderline result and points, but only uncertainly, to liver-cell disease. Since I believe that there is too little evidence of liver-cell disease as the primary trouble, I rather reluctantly relegate hepatitis of any sort to second place.

A better possibility seems to be that the jaundice was due to biliary obstruction. This would adequately account for all the laboratory data presented. In fact, the ratio of direct to indirect serum bilirubin is some slight evidence for jaundice on an obstructive basis. But was the obstruction due to stone within the lumen of the duct or to pressure, presumably from cancer, without? I am sure that there is no way in which we can resolve this question with any certainty. Without doubt, a stone is a real possibility, and it is easy to make the mistake of attaching too much importance to the slender clues that the record contains in favor of cancer. For instance, the fact that the patient had no pain is statistically slightly in favor of cancer. The tip of the spleen was felt. This may occur with either type of obstruction, but again it is a little more frequent with cancer. The clinical course was quite steadily progressive over a total of nearly five months—a picture at least consistent with cancer. Dr. David Riesman used to consider preicteric itching suggestive evidence of malignant obstruction. The liver edge appeared to be abnormally low. One cannot make much of that. It may have been merely ptotic, but if it was really enlarged, it appears not to have enlarged rapidly, for it was said not to have been tender.

Since I must make a diagnosis I shall vote for biliary obstruction due to cancer—the cancer being primary in the pancreas, the ampulla, the gall bladder or even the liver itself. The cancer may have been metastatic, provided the metastasis happened

to develop at the porta hepatis. In addition, the patient probably had rheumatic heart disease and enlargement of the uterus due to fibroids.

It is stated that on the twenty-fifth day an operation was performed. The possibilities of a benign and remediable condition are excellent, and the patient's condition certainly indicated a liver biopsy and probably an exploratory laparotomy.

DR. CLAUDE E. WELCH: Since Dr. Brailey made a diagnosis of cancer, I should like to ask him if he could be more specific. If the surgeon is going to explore, it makes a difference whether the lesion is primary or metastatic. From the history, I think that one can be more specific.

DR. BRAILEY: On a statistical basis, cancer of the head of the pancreas is the most probable, but I should be glad to have you tell me.

DR. WELCH: The gall bladder was not palpable, which is distinct evidence against cancer of the head of the pancreas.

DR. BRAILEY: The patient was a fairly thin person, and the gall bladder might have been expected to be palpable. I do not attach significance to the Graham test. Do you think that nonvisualization is in favor of carcinoma of the gall bladder?

DR. WELCH: No, I do not believe so, because she was deeply jaundiced. No mass was palpable that could be distinctly felt as carcinoma of the gall bladder. She could have had carcinoma of the duct, but that is all she could have had of that nature.

DR. DANIEL S. ELLIS: At the time the Graham test was done, the patient was barely jaundiced. The jaundice seemed to be fading.

DR. BRAILEY: That gives a slightly different picture. I had the impression that she had a fairly steady course.

DR. ELLIS: That is the reason the Graham test was done at the time. Clinically there was enough change to indicate that she seemed to be getting better, and we thought that we might get more evidence from it.

DR. TRACY B. MALLORY: An attempt was made to get additional information on this patient by liver biopsy, which I believe was rather more confusing than helpful. Dr. Ellis, will you take up the story?

DR. ELLIS: This case was one that makes liver disease so fascinating to work with. When the patient was first seen in the office about two weeks before admission to the hospital, the history seemed to be more consistent with a diagnosis of cancer than anything else. One was struck by how well she looked. The stools when first seen were light tan, and she had bile in the urine. I elected to follow her for two weeks at home, the stools became dark, and the degree of jaundice stayed about the same. The itching for practical purposes ceased. At the end of that period, it was believed that there had been no real improvement and that the diagnosis was still not proved. Accordingly, she was admitted to the hospital for aspiration liver biopsy. The tests

referred to above were done on admission, and on the fourth day a biopsy was performed. On the basis of this biopsy report, which Dr. Mallory will describe, we thought that she had intrahepatic disease. The palpable spleen lent more evidence to this diagnosis, and there was no question that the spleen was large enough to be palpable. Largely on the basis of the biopsy report, we elected to give medical treatment for two more weeks.

DR. MALLORY: The aspiration biopsy showed an unusual appearance on which I could not make a diagnosis. The liver cells were obviously abnormal. A portion of them were fat containing, and some were markedly vacuolated but showed a hydropic type of vacuolization rather than that due to fat. That is an unusual finding in biopsy material, and I do not know how to interpret it. There was scanty inflammatory infiltration in the portal areas. I was unable to make a diagnosis of infectious hepatitis, but I did think that there was intrinsic liver disease of some unknown character. That was as far as we were able to go at that time.

DR. ELLIS: On that basis we gave intensive medical therapy, but at the end of two weeks three factors were obvious: the patient was no better, the jaundice was marked, and the stools were clay colored, lighter than before. So far as the laboratory evidence was concerned, she had a rising phosphatase, which bothered us considerably. She started with a low phosphatase but before operation it was up around 15 units. Since she had had the best treatment that we could give her and was getting worse, we decided to perform an exploratory laparotomy. Preoperatively all of us believed that she had intrahepatic disease, the basis of which we hoped would be some obstructive phenomenon that had given rise to an ascending infection and a biliary cirrhosis or ascending cholangitis, although there was a good probability that we would find cancer somewhere.

DR. MALLORY: Dr. McKitterick, can you tell us something about the operation?

DR. JOHN B. MCKITTERICK: I was not present at the operation, which Dr. Leland McKitterick performed. The findings were somewhat unusual in one respect—the patient had a completely col-

lapsed external biliary tree. The gall bladder was just as though one had aspirated it and erupted it of all bile. The common duct was so small that it was almost impossible to get a needle into it. Two or three masses were palpable on the dome of the liver, which to Dr. McKitterick did not feel like metastases. The liver itself was somewhat reddish. The spleen was enlarged. There was some white scarring that was palpable throughout the liver. In the left half of the pancreas, there was a definitely palpable tumor. The liver was biopsied, as was the tumor in the pancreas.

CLINICAL DIAGNOSIS

Carcinoma of pancreas?
Intrahepatic disease?

DR. BRAILEY'S DIAGNOSES

Biliary obstruction, due to carcinoma
Rheumatic heart disease

ANATOMICAL DIAGNOSES

Adenocarcinoma of pancreas, with liver metastases
Biliary cirrhosis of liver, slight

PATHOLOGICAL DISCUSSION

DR. MALLORY: Biopsy of the liver showed that, in the interval between biopsy and operation, the vacuolization of the liver cells, both fatty and hydropic, had entirely disappeared, presumably as the result of the dietary treatment that Dr. Ellis had carried out. In one respect, however, namely, bile stasis, there was no improvement, in fact this was considerably intensified. Bile staining of the Kupfer cells was particularly prominent. The portal areas had become wider, and in many of them we found strands and small clumps of frankly neoplastic cells. Biopsy of the pancreas showed an adenocarcinoma, which was undoubtedly the primary site of the neoplastic disease.

I do not believe that I can explain the collapse of the extrahepatic bile ducts with any certainty. The widespread tumor infiltration of the portal areas within the liver may have produced obstruction of the small intrahepatic bile ducts.

SUBSCRIPTION TERMS: \$6.00 per year in advance, postage paid, for the United States (medical students, \$3.50 per year); Canada, \$7.00 per year (Boston funds); \$8.50 per year for all foreign countries belonging to the Postal Union.

MATERIAL should be received not later than noon on Thursday, two weeks before date of publication.

THE JOURNAL does not hold itself responsible for statements made by any contributor.

COMMUNICATIONS should be addressed to the *New England Journal of Medicine*, 8 Fenway, Boston 15, Massachusetts.

DIAGNOSIS OF AMEBIASIS BY STOOL EXAMINATION

DURING the past year the results of several studies on dysentery and diarrhea in members of the armed forces returning from tropical areas have been published.^{1,2} These indicate to some extent the number of persons who had these diseases while overseas. The majority of these men are no longer in the service, and a certain percentage are being seen by clinicians because of unexplained persistent diarrhea, diarrhea alternating with constipation or vague abdominal symptoms.

Since a variety of causes can be responsible for these intestinal conditions and since the clinical symptoms are frequently nonspecific, it is necessary to find an organic basis or a pathogen responsible

for the condition, with subsequent elimination of the latter if discovered. Although clinicians can explore the physiologic bases for these symptoms by routine procedures and although reliable stool cultures for pathogenic bacteria are readily obtained, there is a scarcity of laboratory technicians skilled for the diagnosis of infections due to intestinal parasites.

The majority of human helminthic infections have a definite geographic distribution. For example, a person who has never been outside New England could not have filariasis or hookworm infection, but a man with a period of wartime service on certain Pacific islands might have become infected with both these helminths. Thus, knowledge about the patient's travels and the conditions under which he lived in endemic areas is helpful in arriving at the possibility of infection and the specific helminthic infection suspected. Unfortunately, infection with *Endamoeba histolytica*, the causative agent of amebic dysentery, is universal, although it is more prevalent in the tropics than in the temperate zones. Consequently, infection with this organism can take place anywhere, if food or water contaminated with the infective cysts is ingested.

In examining a stool for parasites, the technician must be able to recognize not only various stages of the pathogen but also nonpathogenic organism, tissue cells, macrophages and debris. A reliable diagnosis is not readily obtainable because the majority of laboratory technicians are not properly trained or lack the necessary equipment. It is a rare technician who can make a satisfactory diagnosis by following a textbook or laboratory manual. Morphology of the organisms, staining technics and cultural procedures must be learned and mastered. Indeed, practical experience gained during a period of intensive training is usually necessary if the technician's results are to be reliable. In addition, the clinician, intern or nurse should know that fecal samples for examination should be free of antiseptics and urine and should be delivered to the laboratory within an hour. If the stool cannot be examined immediately, it should be placed in the refrigerator, not in the incubator. Furthermore, normally passed stools are preferable if the laboratory technician is not highly skilled. Purged stools

give a higher percentage of positive results, but the presence of tissue cells and macrophages may confuse the novice

Textbooks of clinical pathology, parasitology and tropical medicine give the usual procedures for the recognition of amebas in stools. These include a record of the gross appearance of the specimen, including the presence or absence of mucus, pus or blood. Microscopical examination of a fresh preparation consists of a search for active stages of the protozoa or their cysts, as well as tissue cells, erythrocytes and *Blastocystis hominis* (a nonpathogenic, yeast-like organism). If cysts are present, a presumptive diagnosis can often be made by the examination of an iodine-stained preparation, but films stained by the iron-hematoxylin method are usually required to make a specific diagnosis. Cultivation of the specimen for *E. histolytica* is a useful supplementary procedure, but it is not considered practical for routine laboratory purposes unless the technician has had experience with this technic. Concentration methods, using a saturated solution of sodium chloride or zinc sulfate flotation, are satisfactory for the detection of nonoperculated helminthic eggs and of low concentrations of cystic amebas. It must be remembered, however, that such methods are useful only to detect the cystic stages, not the active stages, which are present in patients with acute amebic dysentery and in a certain percentage of carriers. The complement-fixation test has been improved and is sometimes used to detect the presence of infection with *E. histolytica*, having proved particularly valuable in suspected cases of hepatic amebic infection. It requires skill, and only a few laboratories are equipped to make the test.

Interpretation of negative or positive findings should depend on the clinical symptoms of the patient. Amebas are not passed at a constant rate in the feces, so that a negative finding in one or several specimens does not necessarily mean that the patient is not infected, nor should it invalidate the results of other laboratory examinations. If suspicion of infection with *E. histolytica* persists, additional stool specimens should be examined. Proctoscopic or sigmoidoscopic examination is helpful in recognizing ulceration in the lower bowel. If ulceration is present, scrapings from the crater of

the ulcer should be examined, since this is the likeliest place for the presence of *E. histolytica*. Furthermore, a positive diagnosis for *E. histolytica* in the absence of symptoms indicates that the patient is a carrier, and the organism should be eliminated by a course with an amebicidal drug, because of the danger of transfer of amebas to others.

The above statements have been made not with the view to create alarm regarding the incidence of amebiasis but to point out the need for improved training of hospital laboratory technicians in the performance of stool examinations for the presence of amebas, to discuss briefly the conditions required for a reliable diagnosis and to point out the meaning of positive and negative findings.

THE QUALITY OF MERCY

THE ancient Israelites, who first conceived the idea of one god for all people, were also the first to credit that Being with absolute justice stern as it might be, and later with the quality of mercy. Mercy, so far as we know, had been a scarce commodity in the world up to that period. Sapient man had been in existence for three or four hundred centuries but he had lived by the law of a tooth for a tooth and an eye for an eye and precious little mercy had entered into it.

Mercy, which Webster considers to be "forbearance from inflicting harm; compassionate treatment especially of the suffering or helpless," is an emotional attribute that might be considered almost spiritual. Rarely, if ever, can it be conceded to lower forms of life, yet few men can be believed to be utterly without it.

Animals show only rudimentary social emotions. They care for their young or destroy them, the dog risks his life for his master or languishes on his grave, they hunt in packs. Certain insects lead highly organized community existences and lend mutual aid, as do bees and ants and wasps but except occasionally for the dog to his master or perhaps mated pairs to each other animals do not know the emotion of compassion. That has been reserved for man.

Shakespeare has given us our greatest dissertation on mercy, which, as we all know, "blesseth him that gives and him that takes" The scepter of a king, we are told, shows the might of temporal power

But mercy is above this temporal sway,
It is enthroned in the hearts of kings,
It is an attribute to God himself,
And earthly power doth then show likest God's,
When mercy seasons justice

We had believed, until a few short years ago, that man might be on an upward path, that his moral insight might be keeping pace with his intellectual achievements, but we have learned since then that ethical conduct depends on certain little understood and unreliable factors Too often in man's history it has happened that just as he reached a point in progress where he thought that he might pause and pose for the photographers, at that point the shooting began Man can apparently become without compassion

So the inhabitants of the world find themselves again resuming the search for the causes of man's inhumanity to man Those who are aware of the need are doing it as individuals, as groups, as nations and as organizations of nations Among the leaders in the search must be the men and the professions among men that, knowing most about suffering, have chosen to be greatest in compassion

The profession of medicine, freed to a large extent from mystery and magic, has shown itself for centuries to be the calling of the Samaritan It has combed the battlefield unarmed, seeking only to lighten suffering where it might be found Its followers are in a position where, by themselves and through their organized fellowships, they must expect to share leadership, to set examples and to stir consciences in still another attempt to shape man's destiny according to a pattern of universal tolerance and mercy

OBITUARY

CHARLES FAIRBANKS PAINTER

1869-1947

Dr Charles F Painter died suddenly at his home on January 6, 1947 He was a direct descendant of an old Virginia family, although he was born in Grand Haven, Michigan, on May 19, 1869

On graduating with a degree of A B in one of the earliest classes of the newly founded Johns Hopkins University in 1891, he came to Boston and studied medicine at the Harvard Medical School, receiving the degree of M D in 1895 He was a member of the first four-year class at Harvard Medical School, where he was associated with such well known classmates as Joseph A Capps, Arthur L Chute, E Amory Codman, Harvey Cushing, Elliott P Joslin, Timothy Leary, William H Robey and Franklin W White Harvey Cushing was closely associated with Charles Painter during his four years at the medical school, and it was Cushing who wrote in a letter to his father dated January 31, 1892 "Painter, I like very much He is slow, but hangs on to everything he gets He hails from Great Barrington and is a great big solid whole-souled creature such as one likes to meet."

He served his internship at the Massachusetts General Hospital and later served at the old Children's Hospital, where he was associated with E H Bradford, Robert Lovett and other brilliant orthopedic pioneers of the time He himself became an outstanding orthopedic surgeon and engaged in active practice of this specialty For many years he was surgeon-in-chief at the Carney Hospital

Between 1913 and 1922 he was dean of Tufts College Medical School This was the decade of World War I, with all the turmoil created by that conflict in the field of medical education, and this service indicates Dr Painter's administrative capacity He also had strong literary interests and was always ready to serve on committees or otherwise when these interests could be brought to bear on current problems While dean at Tufts Medical School he created a Chair of the History of Medicine and occupied it himself for a number of years He edited the *Yearbook of Orthopedic Surgery* and served for a long time on the editorial board and briefly as editor of the *Journal of Bone and Joint Surgery* He was president of the American Orthopaedic Association in 1915 and 1916

In 1929 Dr Painter was chosen librarian of the Boston Medical Library, in which position he served until 1937 He continued the high standards of the Library although it was his lot to hold this position during a period of decreasing financial support That he was able to prevent any material reduction of service to the Library members and the public under these circumstances indicates his devotion to the things that the Library stands for and to the Library itself

Dr Painter's death closes the life of a man who was a scholar as well as a physician and surgeon and who became one of the foremost orthopedic surgeons of his day He was a devoted student of medical history and literature, and one may well understand Cushing's comment that he was "a solid whole-souled creature such as one likes to meet"

MASSACHUSETTS MEDICAL SOCIETY

ANNUAL MEETING OF THE COUNCIL

The annual meeting of the Council will be held in the Georgian Room of the Hotel Statler, Boston, on Monday, May 19, 1947, at 7:00 p.m. This meeting will be preceded by the Cotting supper, which will be served in Parlors A and B of the same hotel at 6:00 p.m.

Business

- 1 Presentation of record of the stated meeting of the Council held February 5, 1947 as published in the *New England Journal of Medicine* issue of April 17, 1947
- 2 Reports of standing and special committees
- 3 Election of officers and orator
- 4 Appointment of committees for ensuing year
- 5 Such other business as may lawfully come before the meeting

MICHAEL A. TIGHE, Secretary

NEW HAMPSHIRE
MEDICAL SOCIETY

DEATHS

GREELEY—Philip H. Greeley, M.D. of Dover died December 20, 1946. He was in his seventy-seventh year. Dr. Greeley received his degree from Dartmouth Medical School in 1897. He was a fellow of the American Medical Association.

His widow and two sons survive.

SPRAGUE—Fred A. Sprague, M.D. of Concord died December 3, 1946. He was in his seventy-fourth year. Dr. Sprague received his degree from Baltimore Medical College in 1906. He was a veteran of both the Spanish American War and World War I. He was a fellow of the American Medical Association.

His widow, two sisters and a brother survive.

MISCELLANY

A BORDEN AWARD TO DR. GAMBLE

The Borden Awards, which were established in 1936 by the Borden Company Foundation, Incorporated, to recognize and encourage outstanding research achievements in the United States and Canada, are administered by eight professional and scientific associations, each of which annually selects someone to receive the award who has reported notable research in his particular field.

To the American Academy of Pediatrics is delegated the responsibility of selecting an investigator who has performed outstanding research in the nutrition of infants and children, and for the year 1946 it chose Dr. James L. Gamble, professor of pediatrics at Harvard Medical School and visiting physician at the Children's Hospital, Boston. The citation reads: "For pioneer work over a period of many years in the field of salt and water balances in the human body with particular reference to infants and children."

CORRESPONDENCE

DEPRIVATION OF LICENSES

To the Editor: At a meeting of the Board of Registration in Medicine held March 21, it was voted to suspend the registration to practice medicine of Dr. Frederick J. Butler, 166 Townsend Street, Roxbury. Dr. Butler was cited to a hearing under General Laws Chapter 112, Section B, but was unable to appear because he is a patient at the Boston State Hospital.

At the same meeting, the Board also voted to revoke the registration to practice medicine of Dr. David Ginsburg,

1938 Main Street, Springfield, following his conviction in court of having performed an abortion.

H. QUIMBY GALLUPE, M.D., Secretary
Board of Registration in Medicine

State House
Boston

DDT "POISONING"

To the Editor: The report of a case of periarthritis nodosa, by Drs. William R. Hill and C. Robert Damiani, which appeared in the December 19, 1946, issue of the *Journal*, was read with considerable interest. It was an able and convincing presentation of a case of that rare and little understood disease. If it had been presented as such, it would have been much less sensational, but at the same time would have been a positive rather than a negative contribution to medical knowledge.

The title and conclusions add one more item to the list of source material that has deluded these authors and will delude still others into erroneous diagnoses of DDT poisoning. Such an erroneous diagnosis in itself may well be the cause of fatalities, for example, the man in New Jersey who developed a constricting pain in the chest while spraying DDT. His doctor, believing that DDT was highly poisonous, advised the victim to run up and down out of doors and breathe deeply in the fresh air. The man followed this advice and proceeded to die, but in the face of a history of a preceding coronary heart attack, the preliminary newspaper reports of a DDT fatality were corrected and did not become a part of medical literature.

The circumstances surrounding the exposure to DDT in the present case deserve careful consideration.

(1) The total amount sprayed in the workroom was 150 cc of 6 per cent DDT and presumably the largest portion of this was sprayed hours before the man came to work. No hand sprayer is made which will keep more than a fraction of 1 per cent of the atomized DDT from settling on the walls or floor, either at the moment of spraying or within a few minutes thereafter.

(2) Even with aerosol atomizers, a very large portion settles out quickly and the remainder could not by any stretch of the imagination have concentrated itself in the lungs or on the skin of the victim in a quantity of the magnitude of 1 per cent of the total which he himself sprayed.

(3) This should be recognized as an infinitesimal dose, even from the most carelessly studied cases of DDT poisoning cited. Reference to the works of Neal et al. should be given considerably more weight than the others cited because of a vastly greater background of toxicologic experience, and because Neal's studies are particularly thorough and scientific investigations of DDT toxicology.

The low toxicity of DDT is attested by a wide experience with its use. I have seen men spraying scores of gallons of DDT a day indoors, day after day, and know of men who have done this for upward of a year. I have seen mixing by hand of thousands of gallons of oily solutions of DDT day after day with frequent wetting of arms and hands, with no ill effect.

The supposition that this patient had become sensitized is not supported in any way, not even by history of prior exposure. Tremors are a sign of acute toxicity, develop early and disappear with recovery. In the case cited, tremors did not develop until a month after an insignificant exposure, and a few days before death in a disease affecting the blood vessels of the brain. The offering of tremors as evidence of the validity of the DDT assumption in this case is an indication of faulty logic as well as a misunderstanding of the true toxicity of DDT. This misunderstanding should not be propagated.

This comment is properly divided into two parts. No slightest exception is taken to the clinical, laboratory and pathological description of a death due to periarthritis nodosa. But the title "Death following Exposure to DDT" is considered misleading and false in its implication. The reasoning is based on false and inadequate premises of exposure and known toxicity of DDT. The assumption, repeated in the conclusion, that DDT was the probable cause of the fatal disease in this case and the statement "It is reasonable to assume that DDT possesses allergenic properties and should be included among the drugs capable of producing a sensitizing reaction" are entirely unjustified.

Of all possible explanations of the present case, this one is the most highly imaginative and quite likely to cause harm and confusion in the medical literature

R W BABIONE
Captain (MC), U.S.N

413 Tyler Place
Alexandria, Virginia

Captain Babione's letter was referred to Dr Hill, whose reply is as follows

To the Editor Perhaps the title of this paper is somewhat misleading since death could not be primarily attributed to DDT. Nonetheless, the clinical picture was quite consistent with a sensitization reaction, and the fact that this became manifest less than twenty-four hours after exposure to DDT makes the latter the presumptive exciting agent. The finding of the lesions of periarthritis in the biopsies of the skin and muscle is further evidence of an allergic reaction. It is well known that sensitization may result from infinitesimal amounts of allergenic agents

WILLIAM R HILL, M D

520 Commonwealth Avenue
Boston

BOOK REVIEWS

Diseases of the Skin By George C Andrews, M D Third edition 8°, cloth, 937 pp, with 971 illustrations Philadelphia and London W B Saunders Company, 1946 \$10.00

Dr Andrews has thoroughly revised this new edition of his standard textbook on dermatology. Almost every paragraph has been revised by the deletion of obsolete material and the addition of recent discoveries. Treatment with the sulfonamides, penicillin, streptomycin and other antibiotics has been incorporated throughout the text. Discussions of more than sixty new skin diseases have been added. New chapters have been inserted with the intention of aiding those who desire to take the examinations of the American Board of Dermatology and Syphilology. All prescriptions have been rewritten in the metric system and in Latin so far as practicable. Many new illustrations have been added. The *Standard Classified Nomenclature of Disease*, compiled by the National Conference, has been followed, with minor exceptions. Every effort has been made to keep the classification simple, easy to use and practical. The text is well written and well organized. Special prominence is given to the more frequent dermatoses. A selective bibliography is appended to each chapter. The text is well printed with a good type on good paper, and the illustrations are adequate. This book should be in all medical libraries and should prove useful to all physicians interested in diseases of the skin.

Electrocardiography in Practice By Ashton Graybiel, M D, and Paul D White, M D With the assistance of Louise Wheeler, A M, and Conger Williams, M D Second edition 8°, cloth, 458 pp, with 323 illustrations Philadelphia W B Saunders Company, 1946 \$7.00

This new edition has been revised in the light of recent advances in the subject. A new section on precordial leads has been added in the first part, and illustrations of normal and abnormal multiple precordial electrocardiograms have been introduced throughout the text. The fifth part contains a new series of test electrocardiograms presented in random fashion, for practice in interpretation. Two new topics, unipolar and esophageal leads and the effects of exercise and low oxygen tests, have been added in appendices. Four new tables are of special interest: the first shows the effects of the so-called "indifferent electrode", the second tabulates the disorders of rhythm, the third shows the characteristic changes in the electrocardiogram in various diseases affecting the heart, and the fourth lists the changes resulting from the administration of various drugs and the effect of various physiologic influences. The usefulness of multiple chest leads is fully discussed.

This standard monograph should be in all medical libraries and should prove of value to all physicians interested in diseases of the heart.

Electrocardiography, including an Atlas of Electrocardiograms By Louis N Katz, M D Second edition, thoroughly revised 4°, cloth, 882 pp, with 525 illustrations Philadelphia Lea and Febiger, 1946 \$12.00

The author has thoroughly revised this standard work, bringing up to date the subject matter and the bibliography and rewriting large portions of the text. The additional material has increased the size of the volume about 50 per cent, necessitating the division of the text into twenty-three chapters instead of the sixteen in the previous edition. The illustrations have also been completely revised, one hundred and twenty-five having been deleted and two hundred and forty nine added. Summary tables and new charts showing the salient features of normal and abnormal deflections, of specific patterns and of various arrhythmias have been introduced to make the volume more suitable for beginners. A third chest lead—Lead CF—is described, and its use under various circumstances considered and illustrated, because the author is convinced from his experience in over 5000 cases that this chest lead contributes greatly to the evaluation of abnormalities of the heart, especially of heart strain, intraventricular block and coronary disease.

The report of the special committee of the American Heart Association on the establishment of a universal nomenclature for the several deflections of the electrocardiogram is included, and its recommendations are largely followed with a few exceptions. A new chapter on terminology has been introduced. A section on the principles involved in the electrical manifestations of the heart has been added, and recent concepts of the theory of the electrocardiogram and findings on the properties of the heart have been included in the revision. War experience having shown that the variation in normal electrocardiograms was greater than supposed, the standards of normality have been completely revised and the effect of posture, body build and the physiologic state of the subject have been discussed in a separate section. The chapters on transient electrocardiographic changes in acute and chronic illness and in patients under the influence of drugs have been expanded to include recent information. The conditions giving rise to electrocardiograms simulating the coronary pattern are emphasized in a separate chapter, and coronary pain and coronary circulation have been included to make the subject of coronary disease more complete. The material on the management of cardiac arrhythmias and coronary disease has been expanded for the benefit of the clinician. A new chapter on interference and dissociation has been added, as well as material on several unusual and complex arrhythmias and new information on the nature of intraventricular block and the combination of the shortened PR interval and the prolonged QRS complex.

Despite these major additions and expansions the scope and purpose of the work have not been altered. A selective bibliography is appended to each of the three sections of the text. The book is well printed with a good large type, and the large number of tracings are uniformly clear and distinct. This treatise should be in all reference medical collections.

Nursing in Commerce and Industry By Bethel J McGrath, R N, for the National Organization for Public Health Nursing 8°, cloth, 356 pp New York The Commonwealth Fund, 1946 \$3.00

This volume provides a much needed authoritative up-to-date text in industrial nursing. Mrs McGrath is well qualified for the task of writing such a text, since she was formerly industrial nursing consultant to the National Organization for Public Health Nursing and is chief industrial nursing consultant to the American Association of Industrial Nurses and industrial nurse of the Powers Dry Goods Company, Minneapolis. The book has been planned for the nurse already practicing in the field.

Dr Alice Hamilton, well known authority on industrial poisons, has written an interesting and informative introduction in which she points out the great advances in industrial medicine and nursing that have taken place during the last thirty years. The material is well organized, and the text well written and documented.

The author defines industrial nursing as the application of nursing skill to groups of men and women at their places of work for the purpose of helping them build and maintain their best health, and the rendering of prompt and efficient nursing assistance when they become ill or injured.

The preliminary chapters are devoted to the history of industrial nursing in the United States, industrial organization, the nurse, the nurse's duties and responsibilities and physical facilities for the nursing service, as well as an important chapter on relations with employees and employee organizations.

Then in order follow discussions of the health of the worker, occupational accidents and hazards, disease hazards, non-occupational illness and accidents, mental hygiene, including malingering, sight conservation (written by Eleanor Mumford), orthopedic nursing (written by Katherine Ott), nutrition, problems peculiar to women in industry and the control of communicable diseases. The concluding chapters concerning records and reports were written by Heide L. Henniken, and those on rehabilitation, workmen's compensation, industrial welfare activities and hourly nursing service by an outside agency by Lucille M. Harmon.

An appendix contains important miscellaneous material including equipment for the health service, a concise manual for emergency procedure, a formula for an industrial cleanser, standards for maternity care and employment of expectant mothers, and equipment and technic for eye examinations.

The book is well printed with a good type on good soft paper and is not too heavy for the size of the volume. It has an adequate index. It should be in all medical, public-health and public libraries, as well as in all industrial and commercial libraries.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Cornell Conferences on Therapy, Volume I Edited by Harry Gold, M.D., managing editor, David P. Barr, M.D., Eugene F. DuBois, M.D., McKee Cattell, M.D. and Charles H. Wheeler, M.D. 8°, cloth, 322 pp. New York: The Macmillan Company, 1946. \$5.25.

The topics reported in these informal conferences, first held in 1937, cover the whole field of therapeutics and are a selection from a large number. The following subjects are discussed: the doctor's bag, use and abuse of bed rest, heart failure, digitalis vs. digitoxin, mercurial diuretics, subacute bacterial endocarditis, abdominal distention, intestinal infections, diseases of the eye, poisoning and the Rh factor.

A Textbook of Gynecology. By Arthur H. Curtis, M.D., professor and chairman of the Department of Obstetrics and Gynecology, Northwestern University Medical School, and chief, Gynecological Service, Passavant Memorial Hospital, Chicago. Fifth edition. 8°, cloth, 755 pp., with 455 illustrations, chiefly by Tom Jones. Philadelphia: W. B. Saunders Company, 1946. \$8.00.

This standard treatise has been extensively revised in all but a few chapters. The section on ovarian tumors has been expanded, and in the chapter on other tumors of the uterus, two new topics, sarcomatoid growth of the endometrial stroma and hypertrophy of the uterus, have been added. The endocrinographic disturbances have been co-ordinated into a separate division providing a consideration of the subject in its entirety. Penicillin therapy has been added to the topic of gonorrheal infection. A large number of new photographs and photomicrographs have been added to the text. The book is well printed with a good type on good paper. The illustrations are excellent. It is recommended for all medical libraries as a reference book.

English-French and French-English Technical Dictionary. By Francis Cusset. 16°, cloth, 590 pp. Brooklyn, N. Y.: Chemical Publishing Company, Incorporated, 1946. \$5.00.

This small dictionary with terms in two parts, French-English and English-French, is well organized and printed

with contrasting type on good paper. The text is not limited to single words but has a large number of short word combinations. It is recommended for all library reference collections.

Proceedings Conference on diagnosis in sterility. Sponsored by the National Committee on Maternal Health, January 26-27, 1945. New York City. Edited by Earl T. Engle, Ph.D. 8°, cloth, 237 pp. with illustrations. Springfield, Illinois: Charles C. Thomas, 1946. \$5.00.

The papers contained in this volume of proceedings cover the various aspects of human sterility. Among the topics discussed are semen examination, testicular biopsy, the role of the accessory glands, chronic hemospermia and its treatment with estrogen, endometrial biopsy, basal body-temperature curves, examination of cervical mucus, tubal-patency tests, history taking of infertile couples and a working hypothesis of the mechanism of sterility. The book is well published and is recommended for all medical libraries and for gynecologists and physicians interested in the subject.

Physiotherapy. By Thomas F. Hennessey, M.D., dean and director, Massachusetts School of Physiotherapy. Boston. 8°, paper, 25 pp. Boston: Bellman Publishing Company, Incorporated. 75 cents.

This outline is one of a series of seventy-five occupational booklets used in connection with guidance work. It discusses physiotherapy as a special field in its educational and vocational aspects.

Irish Medical Directory and Hospital Year Book—1945. Eighth edition. 8°, cloth, 296 pp., illustrated. Dublin: The Parkside Press Limited, 1946. 10 shillings, 6 pence.

This reference work is divided into three parts. The first is clinical and contains a number of special articles on delivery, abortion, cancer of the cervix, tuberculosis in infancy, rickets, diarrhea and social service in hospitals. The second comprises an alphabetical list of all physicians in active practice in Ireland, with their qualifications, hospital connections and important medical writings. The third is a list of hospitals in Ireland arranged by county and giving information concerning the administration, number of beds and nurses and public or private status.

Protozoology. By Richard R. Kudo, D.Sc., professor of zoology, University of Illinois. Third edition. 8°, cloth, 778 pp., with 226 illustrations. Springfield, Illinois: Charles C. Thomas, 1946. \$8.00.

This standard textbook first published in 1931, has been thoroughly revised and brought up to date. The chapters on physiology, reproduction and variation and heredity have been largely rewritten and enlarged. New material has been added on major groups and phylogeny, and on collection, cultivation and observation. Sixty-nine new figures have been added, and a detailed comprehensive index ends the volume. Short bibliographies are appended to each chapter. The book is recommended as an authoritative reference work.

Diabetic Care in Pictures. Simplified statements with illustrations prepared for the use of the patient. By Helen Rosenthal, B.S., associate dietitian in the Food Clinic, Boston Dispensary and assistant in medicine, Tufts College Medical School; Frances Stern, M.A. (honorary), chief of the Food Clinic, Boston Dispensary, instructor of medicine, Tufts College Medical and Dental schools; special instructor in dietetics in social service, School of Social Work, Simmons College, and associate in nutrition, School of Home Economics, Simmons College; and Joseph Rosenthal, M.D., chief, Diabetic Clinic, assistant medical director and medical supervisor, Domestic Medical Service, Boston Dispensary, assistant professor of medicine, Tufts College Medical School, and associate physician, Joseph H. Pratt Diagnostic Hospital. 8°, cloth, 150 pp., with 137 illustrations. Philadelphia: J. B. Lippincott Company, 1946. \$2.00.

This manual is written in simple language and is adequately illustrated with photographs, charts and drawings. It is designed for the use of the diabetic patient. The subjects covered include diet, insulin and its reaction, acidosis and

coma, blood and urine tests, skin injuries, and personal and special hygiene, especially of the hands and feet. A short chapter on personal and social factors concludes the text. The ring type of binding employed is not suitable for hard usage in the home. This manual should prove valuable to persons with diabetes when used in conjunction with a physician's instructions.

Famine, Rationing and Food Policy in Cochín. By K. G. Sivaswamy. With medical surveys by Lt. Col. T. S. Shastri and Dr. J. A. Bhat. 8°, paper, 35 pp., illustrated. Royapettah, Madras: Servindia Kerala Relief Centre, 1946. Rs. 3.

In this pamphlet the economics and control of food in Cochín State are discussed. The author advocates a short-range program to arrest deterioration in the health of children and expectant and nursing mothers. Special attention is called to malnutrition and to inadequate diets. The appendices are devoted to statistics.

Rare Diseases and Some Debatable Subjects. By F. Parkes Weber, M.D., F.R.C.P., physician to the German Hospital, London. 8°, cloth, 174 pp., illustrated. London: Staples Press, Limited, 1946. 15 sh.

This collection of thirty-one short articles, mostly reprinted from medical periodicals, covers the whole field of clinical medicine. Among the subjects briefly discussed are dysplasias and dystrophies of the subcutaneous tissue, unusual forms of rheumatoid arthritis, vascular disorders, flushing and blushing, calcinosis, endocrinologic conditions, diseases of the liver and biliary ducts and disorders of the nervous system. There are also short chapters on overnutrition, on the influence of Freud, on euthanasia and on the urge to collect. The volume ends with a short series of epigrams and poems.

NOTICES

MASSACHUSETTS CENTRAL HEALTH COUNCIL

The annual luncheon meeting of the Massachusetts Central Health Council will be held on Thursday, May 1, at noon at the Women's Educational and Industrial Union, 264 Boylston Street, Boston. The subject for discussion will be "Local Health Councils." Several active councils will report briefly on their work, after which Dr. Elmer S. Bagnall, former president of the Massachusetts Medical Society, and Dr. Hugh R. Leavell, professor of public-health administration, Harvard School of Public Health, will open the discussion.

Physicians and other persons interested in any aspect of public health are invited to attend. The lunch will cost \$1.50. Persons who wish to be present should notify the secretary, Mr. Arthur J. Strawson, 1148 Little Building, Boston (HAncock 5480).

TUBERCULOSIS INSTITUTE

A better understanding of the tuberculous patient, with an emphasis on the psychiatric approach to this problem, will be the topic of an all-day institute to be held on May 9 at the Hotel Bradford, Boston. The program has been arranged particularly by the Massachusetts Conference of Tuberculosis Secretaries, an organization composed of professional workers on the staffs of the Massachusetts Tuberculosis League and its affiliated associations. Several other agencies, including the Massachusetts Medical Society, are also sponsoring the meeting.

The program will include a morning session, a luncheon meeting and a panel discussion in the afternoon. Outstanding authorities in the field of tuberculosis and psychiatry have been invited to participate. Inquiries regarding the institute should be addressed to Miss Mabel M. Brown, Program Committee, Cambridge Tuberculosis and Health Association, 689 Massachusetts Avenue, Cambridge.

PHI DELTA EPSILON LECTURE

The first annual Phi Delta Epsilon Lecture at the Hahnemann Medical College, Philadelphia, will be delivered by Dr. Frank H. Lahey, of Boston, on Monday, May 12. Dr. Lahey will speak on the subject "Surgery of the Stomach Duodenum and Jejunum."

HARVARD MEDICAL ALUMNI ASSOCIATION

The annual meeting and dinner of the Harvard Medical Alumni Association will be held at the Hotel Clarendon, Atlantic City, New Jersey, on Wednesday, June 11, at 7:30 p.m., during the sessions of the one-hundredth anniversary meeting of the American Medical Association.

TUFTS MEDICAL ALUMNI DINNER

During the celebration of the one hundredth anniversary of the American Medical Association in Atlantic City, the Tufts Medical Alumni Association will hold a dinner on Wednesday, June 11, at 6:30 p.m., at the Ritz-Carlton Hotel. All alumni and their guests are invited to attend. There will be speakers from Boston and other cities who will discuss the medical school and its activities.

RESIDENCIES IN PSYCHIATRY

Psychiatric residencies have been established at the Pratt Diagnostic Hospital, 30 Bennet Street, Boston, and will be one year in duration. The patients will consist largely of those with neuroses or with emotional or personal complications of disease. There will also be a limited number of patients with psychosis. The residents' work will consist of the diagnosis and workup of the case and the handling and treatment of the patient. About 1500 inpatient and 500 outpatient cases are seen annually.

Applications will be considered from men of good standing of a Class A medical school who have had either a medical or a neurologic internship as a minimum. Applications should be forwarded to Mr. Richard T. Viguers, Administrator.

HUMAN LABORATORY INFECTION WITH VENEZUELAN EQUINE ENCEPHALOMYELITIS VIRUS*

Report of Four Cases

HILARY KOPROWSKI, M.D.,† AND HERALD R. COX, D.Sc.‡

PEARL RIVER, NEW YORK

THE occurrence of human cases of encephalomyelitis due to laboratory infection with Venezuelan equine encephalomyelitis virus was reported for the first time by Casals et al.¹ and by Lennette and Koprowski² in 1943. The course of the disease described by these authors varied from patient to patient, mild, almost ambulatory cases paralleled severer ones in which involvement of the central nervous system was manifest.

Two fatal cases with subsequent isolation of Venezuelan equine virus from the brain tissue were subsequently recorded.^{3,4} One of these cases preceded³ whereas the other occurred during⁴ an epidemic caused by the same virus among horses and mules in Trinidad, British West Indies.^{4,5}

Finally, Gallia and Kubes,⁶ examining the serums of laboratory workers at the Institute of Veterinary Research in Caracas, Venezuela, found high titers of neutralizing antibody against Venezuelan equine encephalomyelitis virus in 10 of 16 cases. In only 1 of the 10 subjects involved, however, were there clinical manifestations that could have been attributed to the virus infection.

The purpose of the present report is to describe 4 human cases of laboratory infection with the Venezuelan virus, in 2 of which, prior to infection, there had been no known direct contact with the virus. The clinical course of the infection varied from a relatively mild disease to a severe infection that gave cause for alarm.

EPIDEMIOLOGY

In the second half of January, 1945, a strain of Venezuelan equine encephalomyelitis virus was obtained from Dr. J. Casals, of the Rockefeller Institute for Medical Research, New York. The virus was inoculated into mice on January 22. On

January 25 the mice became sick and were sacrificed. The brains of the animals were removed, and an infectious brain suspension was distributed into ampules and lyophilized.

These experiments were carried out in an animal house, situated approximately 300 yards from the main laboratory, where all subsequent work with the virus was performed. On January 30 a tube of the lyophilized preparation was rehydrated, and the contents inoculated into a lot of fifty eggs containing developing chick embryos. The majority of the embryos were found to be moribund on the afternoon of January 31, when the embryos were harvested. The infected embryos were homogenized in a Waring blender and then immediately formalized to prepare a vaccine.

The inoculation and harvesting of the embryos was done in a small sterile room to which only the personnel working directly with the Venezuelan virus, consisting of a physician and two assistant technicians, had access.

The eggs from which the infected embryos had been removed were deposited in a pail to which a 5 per cent solution of lysol was immediately added. All glassware and instruments used in the work were placed in a covered enamelware container. Late in the afternoon of January 31 the pail and the enamelware container were removed to the adjacent main laboratory, where three other persons, not connected in any way with the experiments on the Venezuelan virus, were working. On February 1 the pail was removed by a laboratory janitor to a disposal place, and the enamelware pan, containing the infected glassware and instruments, was filled with water and brought to the boiling point and then removed to the laboratory kitchen by the two assistant technicians who, on that day, did not have any further contact with the virus. The physician who was in charge of the work was absent from the laboratory on February 1.

*From the Section of Viral and Rickettsial Research, Lederle Laboratories Division, American Cyanamid Company.

†Assistant director, Section of Viral and Rickettsial Research, Lederle Laboratories Division, American Cyanamid Company.

‡Director, Section of Viral and Rickettsial Research, Lederle Laboratories Division, American Cyanamid Company.

The first two human infections (Cases 1 and 2) appeared on February 2 in the assistant technicians who had been closely connected with the work on the virus. The third (Case 3) appeared in the evening of the same day in a biochemist who had not worked with the virus but who had been present in the main laboratory when the work with the virus was performed in the adjacent sterile room. Finally, the fourth infection (Case 4) appeared during the night of February 2 in a serologist who had not even worked in the main laboratory room, adjacent to the sterile room in which the studies on Venezuelan equine encephalomyelitis were carried on. On one or two occasions daily, however, he had passed the main laboratory room to and from his laboratory. The almost simultaneous occurrence of infection in the 4 patients indicated the presence of a common source of infection. This was strongly suspected to be connected with the work done on the Venezuelan virus, since the virus was known to be highly infectious² and since the only person who worked directly with the virus and did not show any symptoms of disease was the physician in charge, who was known to be immune to Venezuelan virus as a result of a previous infection.²

CASE REPORTS

CASE 1 D I, a 24-year-old assistant laboratory technician, reported that she awoke on February 2 with a general feeling of malaise.* A throbbing frontal headache set in, and she remained in bed the entire day. In the afternoon she developed generalized muscular pains, felt weak, had no appetite and spent a sleepless night in spite of the ingestion of "sleeping pills."

Her condition remained essentially the same during the next day except that, in addition, she complained of pharyngeal irritation. A physician discovered no unusual physical findings and diagnosed the illness as "grippe," although the patient did her best to convince him that she had "Japanese encephalitis." She ascribed this notion to the fact that shortly before the onset of the illness she had been vaccinated with a formalin-inactivated preparation of mouse-brain suspension infected with Japanese B encephalitis virus. The physician prescribed sedatives and sulfadiazine.

On February 4 the patient felt "somewhat better." The headache, pharyngeal irritation and muscular pains persisted but were of diminished intensity. She still had no appetite and complained of drowsiness, although she stated that she was able to sleep only after taking large doses of "sleeping pills."

On February 5 the patient felt much better. The pharyngeal irritation, muscular pains and drowsiness disappeared, but a slight frontal headache remained. She asserted that she still felt weak and had no appetite. It is assumed, however, that convalescence began on that date (February 5), for 3 days later the patient was symptom free except for weakness. She reported back to work on February 14, stating that she had been too weak to make the trip to the laboratory before that date.

CASE 2 D J S, a 22-year-old assistant laboratory technician, was well until about 10 a.m. on February 2, when she suddenly developed malaise and generalized body aches. The face was hot and flushed, and the whole body felt warm. The temperature was 101.1°F. After a specimen of the blood had been taken, the patient left the laboratory and went home to bed. She felt extremely drowsy and developed an almost unbearable headache localized between the eyes. Generalized body aches persisted, and she developed mild photophobia.

She had no appetite but slept the entire night. The next day her condition remained unchanged, and a physician made the diagnosis of "grippe" and prescribed sedatives and sulfadiazine. The appetite remained poor, and the patient was quite weak. On February 4 she awoke feeling much better since all the symptoms, except the frontal headache, had diminished. On the following day she suffered a slight relapse and again felt feverish, the headache became more accentuated and the feeling of malaise returned. The symptoms subsided in the evening, however, and she spent a restful night. On February 6 she spent an afebrile day and had few complaints. She still felt weak, but her appetite was normal.

Recovery was uneventful, and the patient reported back to work on February 15.

CASE 3 D W McK, a 34-year-old biochemist, developed the illness on February 2, when at about 7 p.m. he suddenly noticed that he felt more tired than usual. During dinner he was conscious of a "lightheaded feeling," and a throbbing frontal headache soon appeared that was accompanied by a bothersome pharyngeal irritation. The headache became progressively worse, and at about 10 o'clock he started to have paroxysms of chills that lasted almost uninterrupted for 2 hours. He had profound mental depression and during the night was feverish and delirious, at 3 a.m. he vomited partially digested food stained with bile. On the following day his condition remained unchanged except that he complained of muscular pains chiefly localized in the calf muscles. He was seen by a physician, who prescribed penicillin by mouth and a cough syrup containing codeine. In the afternoon a specimen of blood and a throat washing were taken. The patient slept during the 2nd night, and the temperature declined in the afternoon of February 4. The headache became less intense, but muscle and joint pains and pharyngeal irritation persisted.

On February 5 a macular rash appeared over the abdomen, inguinal folds and buttocks. The rash disappeared on the next day, and it was subsequently discovered that the patient was apparently sensitive to codeine, the administration of which had presumably caused the rash. The intensity of the systemic symptoms declined gradually throughout February 5 and 6.

On February 7 he awoke without the previous symptoms but developed complete anosmia and agusia that persisted for 2 weeks and disappeared spontaneously.

On February 12 the patient resumed work at the laboratory.

CASE 4 † D W, a 36-year-old serologist, awoke on February 3 at about 4 a.m. with a shaking chill. The temperature was 102.9°F. A throbbing ache appeared over the occiput and in both eyes, and he experienced generalized muscular and joint pains. During the following 8 hours the patient had three more shaking chills, and the headache became severe and predominantly frontal and retro-orbital. The muscle pains became localized in the lumbar region. Since the patient had been working with material containing living *Rickettsia orientalis* during the period immediately preceding the illness, the possibility of scrub typhus infection was suspected, and he was hospitalized about 7 hours after the onset of symptoms.

Physical examination disclosed a well developed and well nourished man who appeared acutely ill. The temperature was 103.5°F, and the pulse rate 106. No abnormalities except tachycardia and a fairly loud blowing systolic murmur between the sternum and the apex of the heart were discovered. The total white-cell count was 10,600. A blood sample was obtained from the patient for bacterial culture and inoculation of animals.

At 5 p.m. the patient was still acutely ill and uncomfortable, with a severe throbbing headache, photophobia and profuse sweating. The temperature was 101.3°F, and the pulse rate 110. In spite of the fact that the patient had no rash, his condition was tentatively diagnosed as scrub typhus fever, and medication with methylene blue† — 20 gm. per day — was started at 8:15 p.m. One hour after taking the first 0.5-gm.

†Reported through the courtesy of Dr. Walsh McDermott of the Department of Medicine, Cornell University Medical College.

†Medication with methylene blue was based on the work of Petersen and Fox⁷ who observed survival of mice infected with scrub typhus following treatment with the agent.

*The description of this case presented certain difficulties because the patient was highly susceptible to suggestion.

case, the patient became nauseated and vomited some of the drug.

On February 4 the patient was definitely improved, although he was still uncomfortable with a headache, muscular pains and pain in the calves. The temperature at 9 a m was 99.5°F, and the pulse rate 102 per minute, the total white-cell count was 5500. After another 0.5-gm dose of methylene blue, the patient vomited, and the dosage was cut down to 0.25 gm every 3 hours. On this dosage he was still nauseated but did not vomit. He also received two doses of 0.3 gm of codeine sulfate. At 9 p m the temperature was 101.1°F.

On the following day the patient continued to improve. The temperature at 8 a m was 99.1°F. The headache had virtually disappeared, and the muscular pains and backache were of diminished intensity. Methylene blue was continued (0.25 gm every 3 hours), and nausea persisted.

On February 6 the patient's condition had further improved. The temperature was 99.9°F at 7 a m. Since the results of the inoculation of the patient's blood into animals indicated that the diagnosis of scrub typhus fever was not probable, the administration of methylene blue was discontinued.

On the morning of February 7 the temperature was still 99.9°F. Examination of the urine revealed red cells and 15 to 20 white cells per high-power field in the sediment. This was considered to indicate cystitis or urethritis, possibly provoked by the ingestion of methylene blue.

During the next few days the patient's condition, except for a slight headache, remained essentially normal. The temperature averaged 100.4°F, and the white-cell count between 6400 and 8000.

On February 14 the severe headache recurred during the afternoon. The white-cell count was 14,000, but the patient was still almost afebrile. Lumbar puncture yielded a crystal-clear fluid. No bacterial organism was cultivated from the spinal fluid, and a complete laboratory analysis yielded practically negative results. Red cells were still present in the urine, although in diminished numbers. During the next day the patient's condition was practically normal except for a feeling of weakness and dizziness on standing. These symptoms gradually disappeared, and the patient was discharged from the hospital on February 23.

After discharge, recovery was uneventful, and the patient reported back to work on March 1.

ISOLATION OF THE VIRUS

No blood was obtained from the patient in Case 1 during the illness. Blood was obtained on the first day of the illnesses in Cases 2 and 4, and on the second day in Case 3.

Each specimen of serum was injected intracerebrally in amounts of 0.03 cc into 6 albino Swiss mice twenty-one to twenty-eight days of age. All the inoculated mice were either sick or dead forty-eight hours after inoculation, and the survivors were sacrificed. The brains were removed, and a suspension was prepared according to a technic described elsewhere.² The bacteriologically sterile suspensions were then distributed in ampules, lyophilized and stored for five months at 4°C.

In addition, a throat washing obtained from the patient in Case 3 on the second day of the illness was inoculated intranasally in 0.05-cc amounts into 10 mice. The majority of the mice were sick on the sixth day after inoculation. The sick mice were sacrificed, and since the lungs were normal on gross examination, the brains were removed and dealt with as mentioned above.

Five months later an ampule of each of the four strains was rehydrated with physiologic saline solution, and the contents were inoculated intracerebrally into mice. Forty-eight hours later, when the

mice were moribund, the brains were removed and a 10 per cent suspension by weight was prepared in a TenBroeck grinder. The suspensions were centrifuged for fifteen minutes at 1500 r p m in an International Size 1 machine equipped with an angle head, and the resulting supernatants were filtered through a Seitz EK pad, through which 20 cc of normal rabbit serum and saline solution had previously been passed.

Serial tenfold dilutions of the four filtrates were made and tested for infectivity by the inoculation of albino Swiss mice, eighty to one hundred and twenty days old, with 0.03 cc each by the intracerebral and intraperitoneal routes, respectively.

Rabbits, 1.4 to 2.3 kilograms in weight, were also injected with the filtrates, 2 animals being used for each of the 10⁻⁵ and 10⁻⁶ dilutions. All rabbits were injected by the intra-abdominal route with 1.0 cc of the material.

The LD₅₀* titers of the four filtrates in mice varied between 10^{-5.5} and 10^{-3.5} by the intracerebral route and between 10^{-7.0} and 10^{-8.2} by the intraperitoneal route (Table 1). Thus, with the exception of Case 2, the intraperitoneal LD₅₀ titer was only one log lower than the intracerebral. These results indicated that the causative agent readily passed the Seitz filter, and that it was of high invasive power for adult mice inoculated by the parenteral route.

The results of inoculation in rabbits (Fig. 1) further confirmed the highly invasive power of this filterable pathogen. All the animals reacted with fever and succumbed after a fulminant course of disease, with manifestations of marked cerebral involvement such as tremors, ataxia, clonic convulsions and paralysis, the rabbits died seventy-two to two hundred and sixteen hours after inoculation.

After the experiments had been concluded it became clear that the causative agent was a virus of neurotropic properties and of lethal action for adult mice (eighty to one hundred and twenty days old) and for rabbits, even when inoculated in a high dilution by the parenteral route. The Venezuelan equine encephalomyelitis virus seemed to correspond most closely to these characteristic properties,² and an attempt was therefore made for further identification.

IDENTIFICATION OF THE VIRUS

Neutralization tests were performed with the four infectious agents recovered from Cases 2, 3 and 4 and with serum from a rabbit that was known to be immune to Venezuelan equine encephalomyelitis. Normal and immune serums of the same animal were used in each case. The same rabbit serums had been used in previous experiments for identification of human strains of Venezuelan virus.² The technic of neutralization test followed exactly that previously described,² except that adult mice eighty to one

*LD₅₀ represents the dilution of virus of which 0.03 cc. will kill 50 per cent of the mice within the test period.

hundred and twenty days of age, inoculated by the intraperitoneal route with 0.05 cc of the respective virus dilution, were used throughout the study. Five mice were injected with each dilution. The test, with the agent recovered from Case 4, was done in duplicate, the second test being performed by Dr. J. Casals, of the Rockefeller Institute for

toms. Blood was obtained from the patient in Case 4 on the thirty-fourth day after the onset of symptoms. These convalescent-phase serums were compared for neutralizing capacity with acute phase blood specimens obtained from the patient in Cases 2, 3 and 4 on the first and second days of illness. To eliminate the presence of living virus

		Immune*	—	0/4	0/4	0/4	0/4	0/4	—	—	—	—	10 ^{-2.8}	

*Test performed with normal and immune guinea pig serums by Dr. J. Casals, of the Rockefeller Institute for Medical Research. Guinea pigs instead of mice were used in the neutralization test.

firmed these findings, from which it may be deduced that the infectious agent was identical with the virus of Venezuelan equine encephalomyelitis virus.

APPEARANCE OF NEUTRALIZING ANTIBODIES

Blood was obtained from the patients in Cases 1, 2 and 3 at intervals of nineteen, nineteen and eighteen days, respectively, after the onset of symp-

in the neutralization test. The procedure of the test followed that described above.

The results of the test are presented in Table 3. The titer of the virus in the presence of acute-phase serums ranged from 10^{-7.6} to 10^{-8.2}. In the presence of convalescent serums the LD₅₀ titer of the virus was 10^{-1.0} or lower in Cases 2, 3 and 4 and 10^{-1.6} in Case 1. Thus, even in Case 1, in which no serum

sample obtained during the acute phase of the disease was available for comparison, it may safely be assumed that the patient on February 20, was immune to the Venezuelan equine encephalomyelitis virus

The development of antibodies in patients during their convalescence in concentrations neutralizing

this laboratory In 1938 the V-1938^s strain of the virus was brought, for the first time, from Venezuela to the Lederle Laboratories and worked with for a period of about two years.⁹ Although no signs of infection were observed among persons working with the virus at that time, it seemed to be of interest to examine the serums of those connected

FIGURE 1

130,000 or more minimal lethal doses of the Venezuelan virus is additional evidence that the human infections were due to this agent

RESULTS OF NEUTRALIZATION TESTS IN PERSONS PREVIOUSLY EXPOSED TO VIRUS

The present infection was not the first occasion on which the Venezuelan virus has been brought to

with the work for the presence of neutralizing antibodies directed against the Venezuelan virus. Blood was obtained from 3 of these persons (W T, J M and J K) who were still working in the Laboratory and from another (H R C), who had worked on the isolation of the virus from Case 4 of the present series. Blood was also obtained from 2 persons (M P and J B) who had been working in the

same room as the patient in Case 3 and who, although not in direct contact with the virus, had become sick with symptoms consisting of fever, headache and muscular pains almost simultaneously with the positively diagnosed cases described above. As a positive control of the test, a serum sample was obtained from one of us (H K) who had had

been infected or because the amount of neutralizing antibodies in the blood had decreased below a detectable level.

DISCUSSION

As mentioned above the Venezuelan virus was handled in this laboratory on only two occasions:

Venezuelan equine encephalomyelitis in July, 1943.²

The technic of the test was the same as that described above.

The results are shown in Table 4. It will be observed that the titer of the virus, in the presence of immune serum of H K, was lower than 10^{-3.0} whereas in the presence of serums obtained from other persons, the titer ranged from 10^{-7.0} to 10^{-8.5}.

before it became the cause of human infections. On the first occasion, the work was carried out in the animal house to which 2 patients (Cases 3 and 4) did not have access at that time. Thus, it seems probable that these patients, as well as the other 2, became infected when the virus was handled in the main laboratory—that is, sometime between January 30, when a tube of lyophilized

— the usual titration end point of the virus in the absence of neutralizing antibodies.¹⁰

It may be assumed that the sickness of M P and J B was purely coincidental and that H R C, in spite of a recent direct contact with the Venezuelan virus, did not develop humoral immunity directed against this virus. Also, none of the persons (W T, J M and J K) who had worked with the virus in 1938–1940 showed demonstrable specific antibodies in the blood, either because they had not become in-

material was opened for inoculation of eggs, and February 1, when the eggshells and glassware and instruments used for harvesting of the chick embryos were disposed of. This would bring the incubation time of the disease in human beings up to three or four days, which is not improbable when compared with previous findings.²

The puzzling feature of the present report lies, however, in the fact that 2 patients became infected without having had any direct contact with

the virus. Moreover, as mentioned above, 1 of the patients (Case 4) did not even work in the same laboratory room in which work with the Venezuelan virus was carried on. Between January 30 and February 1 the work with Venezuelan virus was carried on in fertile eggs only, so that the latter must be considered the source of the infection in human beings. In view of what has been stated above, contact infection seemed to be out of the question, leaving inhalation of infectious material as the most probable route of infection. The type of infectious material that may have been inhaled by all 4 patients cannot be determined. One may speculate whether or not a small amount of the embryonic suspension spilled during blending, dried in the air

direct isolation of the virus, whereas the remaining 14 cases were diagnosed on the basis of the appearance of antibodies in the blood of the subjects. As further shown in Table 5, only 2 cases—those described by Randall and Mills³ and Gilyard⁴—occurred naturally, and they have been the only fatal cases reported so far. Of the remaining 24 cases, 14 were definitely due to laboratory infection, whereas the remaining 10 cases reported by Gallia and Kubes,⁶ were attributed to infections of probable laboratory origin, although since the respective subjects lived in Venezuela, there remains the possibility of an inapparent natural infection. In the entire series of 26 cases, besides the 2 fatal ones 2 patients showed symptoms that were regarded as severe, 13

and subsequently was inhaled by the patients, or whether some of the infected eggshells were crushed outside the containers and the resulting dust inhaled by the patients. Whatever the true fact may be, all speculations remain within broad limits of probability.

Nothing characteristic was observed about the course of the disease, which was similar in its signs and symptoms to that described by other authors.^{1,2} Fever, body aches and pains and a rather persistent and severe headache were common to all cases. Again, as described earlier,² 3 of the patients were believed to have had attacks of "grippe," the fourth being properly diagnosed only because of the patient's hospitalization.

Marked differences in the severity of the illness were also observed in the present series. Cases 1 and 2 were the least severe, whereas Case 4 was so severe as to give cause for alarm and, because of its severity and its period of remission, closely resembled Case 7 of the previous report.² In all the present cases, the course of the disease seemed to be severer than that described by Casals and his associates.¹

Since the cases described above increased the number of cases of human infections reported in the literature as due to Venezuelan virus to 26, all observations related to that infection in human beings were tabulated (Table 5). It may be observed that of the 26 cases reported, 12 cases were diagnosed by

had mild symptoms and 9 had no symptoms, although the serums neutralized the Venezuelan virus.

The facts that the only 2 fatal cases of Venezuelan encephalomyelitis occurred during an epizootic in Trinidad^{3,4} and that no known accidents were associated with the laboratory infections raise the question whether the relatively low infectiousness of the Venezuelan virus, observed in the latter cases, was related to the unnatural intranasal spread of the infection.* The human infections that occurred during the epizootic were, in all probability, caused by the bite of an infected mosquito, and the intracapillary route of infection may have resulted in a much more fulminant spread of the infection, ending in the death of the patients. On the other hand, the lack of reports of fatal human cases occurring among the inhabitants of Venezuela residing in regions where the virus is enzootic must be considered.

The invasive power of Venezuelan equine encephalomyelitis virus for man is high and yet its virulence for man apparently remains comparatively low. The report of 2 fatal cases,⁴ however, and the ease with which the virus causes laboratory infection indicate the caution that must be exercised in working with the pathogen.

*Further evidence for the intranasal route of infection is suggested by the fact that all attempts to isolate the virus from throat washings (Table 5) were unsuccessful.

SUMMARY

Four cases of human infection with Venezuelan equine encephalomyelitis virus are reported. All were due to infection acquired in the laboratory. The virus was isolated from the circulating blood in 3 cases and from the throat washings in 1.

The diagnosis in these 3 cases as well as that in another was further substantiated by the appearance of specific neutralizing antibodies in the convalescent sera. These findings are discussed in the light of previous reports of human infection due to Venezuelan equine encephalomyelitis virus.

A SURVEY OF THE FIRST THREE MONTHS OF OPERATION OF A VETERANS ADMINISTRATION MENTAL-HYGIENE CLINIC

MORRIS H. ADLER, M.D.,* AND EDWARD M. L. BURCHARD, PH.D.†

BOSTON

SINCE the Mental Hygiene Clinic of the Veterans Administration began operation in Boston on March 18, 1946, a number of questions have been asked concerning the management of patients, the therapeutic goals, the types of patients who present themselves for treatment, the results and so forth. Although it is too early to permit an adequate reply to all the inquiries, a survey of the first three months' activities may clarify somewhat the work and aims of the clinic.

Since its opening the clinic has grown steadily both in patient load and in staff, although no attempt has been made to publicize its existence. At the time of writing further expansion has been stopped by lack of sufficient space for treatment rooms. At present the clinic is housed in a wing of the West Roxbury Veterans Hospital, which it fills to overflowing. On completion of more spacious quarters, an increase of more than twice the present number of patients treated will immediately be possible.

The staff consists of three full-time psychiatrists, four part-time psychiatric consultants, three full-time psychologists, five full-time psychiatric social workers and an office force of appropriate size. The move to larger quarters will permit the staff to be augmented immediately by four psychiatrists, a psychologist and three social workers. The eventual size of the staff can only be guessed at, since its further increase will depend entirely on the number of patients.

All patients referred to the clinic from any source are accepted on a trial basis without preliminary

screening. This is admittedly a generous admission policy, but in the initial stages of operation, it provides the only method of determining the types of patients that can be referred to a mental-hygiene clinic.

A broad base for referrals is being obtained, practically every community organization with which a veteran can be expected to make contact

being represented. It is not surprising that by far the majority of patients are referred by some division of the Veterans Administration, but it is gratifying to note that of 228 patients, 19 were self-referred and 15 were referred by private physicians (Table 1).

Such an admission policy may be expected to give the clinic a high percentage of cases that will eventually prove to be therapeutic failures, but it is regarded as preferable at our stage of development

*Chief psychiatrist, Mental Hygiene Clinic, Veterans Administration, Boston.

†Chief psychologist, Mental Hygiene Clinic, Veterans Administration, Boston.

not to have any predetermined diagnostic or other criteria for refusing new applicants for psychiatric assistance. Several factors have dictated this decision. In the first place, it has been the experience of military psychiatrists that patients who in civilian practice would be considered poor material for treatment respond to psychotherapy. Secondly, it is believed that this clinic should take the lead in the development of new therapeutic devices and techniques of potential benefit in the management of patients hitherto considered resistant or unamenable to psychotherapy. A final reason for accepting all types of patients was that this practice keeps the clinic from becoming too one-sided and makes available a large and varied group of patients for teaching purposes.

So far as the legal aspects of this policy are concerned, eligibility for treatment has been established by Veterans Administration Circular No. 26, which, in effect, gives authority to the chief medical officer to determine whether or not a patient is eligible for psychiatric care. This permits immediate psychiatric care of veterans with service-connected disabilities, prior to completion of adjudication of their claims. A great advantage is that the policy avoids over-stress of symptoms in the hope of receiving treatment. The veteran is not made to believe that he must exhibit extreme and dramatic evidences of his illness to be treated. The clinic is thus enabled to do prophylactic work, instead of limiting itself to patients who had already suffered symptoms and had been hospitalized for them while in military service.

Despite this "open-door" policy, the great majority of patients fall into the general grouping of psychoneurotic disorders, only 15 of a total of 228 cases being classed as character and behavior disorders that are generally not amenable to treatment (Table 2). The high percentage of anxiety reactions agrees with the general experience of clinics and psychiatrists treating veterans.

Since our methods of managing patients are rather different from those in use in other mental-hygiene clinics, a short description of the procedures is of interest. On referral the patient is immediately given an appointment for the orientation class. Orientation sessions are held three times a week, and thus the initial contact with the clinic staff need never be delayed more than twenty-four hours. The orientation session, which is conducted by a psychologist and lasts an hour, is designed to answer the veteran's questions about clinic procedure and rules, methods of treatment, what he can expect to be done for him and what the clinic will expect from him. An attempt is also made in this first session to relieve some of the anxiety about the label "psychoneurosis" and to give the patient a rational and acceptable, although superficial, explanation for some of his symptoms.

After orientation, a complete history is obtained by a social worker—this usually requires two appointments and may extend to three or four in complicated or retarded cases. Such an extended period with the social worker has proved to be extremely valuable in the management of treatment. Not only can the treatment be speeded up because the psychiatrist has available a complete case history before he sees the patient but also the interview with the social worker serves as superficial psychotherapy in itself. The patient is forced into a biographical orientation that prepares him for more

searching therapy and frequently results in some reorientation toward his complaints before the initial contact with the psychiatrist. Furthermore, these interviews serve as a screening device for patients who are so unprepared for psychotherapy that they cannot even co-operate in the giving of biographical information at the conscious level.

After the history has been taken the patient sees a psychiatrist for a survey, at which time the tentative diagnosis, prognosis and program of treatment are determined.

Treatment may take the form of individual psychotherapy in addition to environmental manipulations, individual psychotherapy, individual psychotherapy with Pentothal Sodium as an adjuvant, hypnotherapy or group therapy. The type of therapy depends solely on the psychiatrist's judgment of what will benefit the patient most and the original program may be modified several times according to the patient's progress and responsiveness.

Since the great majority of patients respond reasonably well to individual psychotherapy with occasional sessions of Pentothal or hypnosis, this is the most frequently used method of treatment. Environmental manipulation is seldom utilized because of our deliberate policy of treating the patient

SUMMARY

Four cases of human infection with Venezuelan equine encephalomyelitis virus are reported. All were due to infection acquired in the laboratory. The virus was isolated from the circulating blood in 3 cases and from the throat washings in 1.

The diagnosis in these 3 cases as well as that in another was further substantiated by the appearance of specific neutralizing antibodies in the convalescent sera. These findings are discussed in the light of previous reports of human infection due to Venezuelan equine encephalomyelitis virus.

being represented. It is not surprising that by far the majority of patients are referred by some division of the Veterans Administration, but it is gratifying to note that of 228 patients, 19 were self-referred and 15 were referred by private physicians (Table 1).

Such an admission policy may be expected to give the clinic a high percentage of cases that will eventually prove to be therapeutic failures, but it is regarded as preferable at our stage of development

*Chief psychiatrist, Mental Hygiene Clinic, Veterans Administration, Boston.

†Chief psychologist, Mental Hygiene Clinic, Veterans Administration, Boston.

Since the 28 per cent of patients who voluntarily ceased treatment before they were discharged in a sense constituted failures, this group was surveyed as intensively as the records permitted. In both diagnosis and source of referral the patients were not distinguished from the remainder treated. We were struck with the fact that 25 per cent of the group ceased reporting to the Clinic before they had made any contact with a psychiatrist and that

of the professional staff. Once a week a staff conference lasting an hour is held for psychiatrists and psychologists. At each meeting a member of the staff presents a case currently being treated. The dynamics behind the symptoms, the treatment program, the therapeutic technics and so forth are discussed and criticized by the entire staff. At these meetings, such considerations as problems of diagnostic nomenclature, sources and methods of

an additional 30 per cent failed to return after the first treatment interview. After the third hour of treatment the rate of attrition dropped off steeply, only 16 per cent of patients being lost. These findings strongly suggest that the patients ceased treatment because they were disappointed to find that the staff possessed no magical serums or formulas by means of which all their problems could be quickly and painlessly solved. The discovery that psychiatric treatment may be an uncomfortable process was probably too much for them, and they decided that to endure their symptoms would be less disturbing than to face them. It is to be expected that most of these men will return to the Clinic when their symptoms become severer, and a few have already done so. A survey is being conducted by the Social Service Department to discover the specific reason for discontinuance in these 67 cases.

Questions have been asked about the staff-training program and therapeutic goals. A definite educational program has been set up for all members

referral and the relative efficacy of various methods are brought to the attention of the staff.

For the social workers on the staff and those assigned to the Out-Patient Department two weekly seminars of an hour and a half each are held. Although primarily designed for social workers, the seminars may be attended by other staff members who are free at the time. In these seminars clinic plans, methods and procedures, basic psychological theory, the history of and the underlying dynamics involved in various anamnestic and therapeutic technics are discussed. Also, in each session, a complete case is discussed with emphasis on the dynamics and on the clues to dynamics that can be picked up during history taking.

A word about our therapeutic goals may be of interest. We are not deluding ourselves with the belief that a large proportion of patients will be cured in the relatively short period of treatment that has been set up as the maximum. Our experience, however, convinces us that an active therapeutic approach will enable us materially to improve the condition of a high percentage of

to as great an extent as possible exactly as if he were being treated by a psychiatrist in private practice. As a matter of policy, fifty hours of treatment has been set as the maximum, and it is our hope to render patients comfortable and symptom free in much less time.

Although it is too early for any definitive statistics on length of treatment, after three months' work, the Clinic has begun to build up a small but not inconsequential number of patients who have been treated for ten, fifteen and even twenty-eight hours (Table 3). Only a longer period will tell how

successful the treatment of such patients has been. These clinic "veterans" may have built up too great a dependence on the psychiatrist, although clinical judgment in these cases does not support this opinion. Rather, it seems that these men, who are being carried for longer periods, continue to come because they are gaining real—although limited—insight and increased skill in handling their interpersonal problems.

Group therapy is frankly being used as a socializing technic with patients diagnosed as character and behavior disorders who do not respond well to individual treatment. It is a psychiatric commonplace that psychopaths are resistant to uncovering and interpretation procedures because of a warped development that has resulted in improper or inadequate identification with parental authority images. We are giving such patients group therapy with the expectation of making therapeutic use of sibling relationships, which usually develop in such groups.

Groups of 6 to 8 patients are formed with a psychologist as group leader. Each group meets twice a week for an hour at a time for six weeks. The group leader is prepared with a set of twelve short lectures on topics designed to elicit group discussion of troublesome interpersonal problems. Although the lectures are educational in themselves and correct many frequent misapprehensions, they

are not considered treatment in themselves but are regarded as providing a stimulus for an atmosphere in which therapy can take place through group stimulation, development of sibling relationships and identification and recognition by each patient that his problem is not unique and individual but that he suffers from frequent symptoms with which his fellow sufferers can help him.

Each session is opened by a short presentation, lasting ten or fifteen minutes, of a triple-barreled topic designed to correct misapprehensions, elicit discussion and encourage emotional ventilation. Group discussion of the subject is invited and stimulated, the group leader serving as moderator but remaining unobtrusive so long as the patients continue to discuss any potentially therapeutic topic. At the end of the hour the leader summarizes the discussion and relates it to the specific problems of the men in the group.

Since the major purpose of group therapy is to develop sibling relationships, if a patient fails to keep an appointment for group therapy, one of the other patients who lives in his neighborhood endeavors to find the reason for his absence and to persuade him to return. It has been the policy of the Clinic not to have any member of the staff follow up patients who have ceased keeping their appointments. To do so would introduce an authoritarian element that, we believe, would disturb the type of emotional climate that we have been endeavoring to build up in the Clinic situation.

Our group-therapy program is considered effective in several ways, in addition to the building up of the sibling relationships and identifications mentioned above. Relaxation from tension, ventilation of hostility and aggression and considerable catharsis take place. Some patients obtain sufficient insight to become amenable to individual therapy after completion of a course of group therapy, others respond adequately to a simultaneous combination of group and individual therapy, attending group sessions twice a week and seeing a therapist once. Thus, group therapy is employed not only as treatment per se but also as a preparation for, and an adjuvant to, individual treatment.

The results obtained are demonstrated in Table 4, which summarizes according to diagnosis the disposition of all cases in our files on June 30, 1946. Fifteen per cent of the total were either discharged or referred to other agencies for indicated treatment, 28 per cent voluntarily ceased keeping appointments, and 55 per cent were being carried in treatment status. All diagnoses were represented to about the expected extent in each group, and the small number of discharges is to be expected from the short life of the Clinic. Our records show that the patients discharged as "improved" had been given an average of six and a half hours of treatment, and those discharged as "unimproved," five and a half hours.

On August 23, the carbon dioxide snow was administered. A week later the child returned because of failure of the lesions on the right forearm and left leg to respond. The lesion on the right forearm was 4 cm. long, red, raised and circinate (Fig. 1). Freezing therapy was again instituted. When the patient was seen last on September 13, the eruption on the left leg was still present.

CASE 2 R. C., a 5½-year-old boy, was first seen at the Department of Tropical Medicine, Harvard Medical School,

played in a pit in which cats were known to have defecated about thirty new, red, raised bumps were noted on the arms and legs. These lesions apparently appeared within 4 hours after the child became infected. As before, the macules were nonpruritic until the elongation of the burrows was apparent. Thereafter, the child was annoyed by itching. About August 1 the family left Georgia for a visit to the grandparents in New Hampshire. Owing to the severe itching, a physician was called to see the child. Two weeks later a differential count revealed an eosinophil count of 40 per cent. Because

FIGURE 1 Case 1

This photograph of the right forearm was taken on August 30. A central area of granulation tissue is present in the area that had received carbon dioxide-snow therapy one week previously. The burrow proximal to this had almost healed. The distal lesion appeared after therapy.

on August 31, 1946. He had been referred by a physician because of a skin rash on the legs and arms.

The child had been without complaints until the middle of July, 1945. At that time, he was at home in Savannah, Georgia, where he frequently played in the yard without shoes or stockings. One evening when he came home his mother noticed raised red "bumps" on his forearms and legs. These apparently did not itch. In 24 hours the lesions began to progress and became extremely pruritic. The family physician made a diagnosis of "creeping eruption." Ethyl chloride was applied locally for about 1 minute to each lesion. This therapy was repeated almost every 4 days until October 1, when there were no more active burrows. The patient remained well until July, when, after he had

of lack of familiarity with this form of skin disease the child was referred to the Harvard Department of Tropical Medicine.

Physical examination revealed about thirty irregularly serpiginous lesions on the arms and legs that showed some evidence of excoriation. The child was not febrile, and there was no other evidence of disease. A stool specimen obtained at that time revealed no intestinal parasites. Ethyl chloride therapy was again instituted, with almost immediate relief and eradication of most of the lesions.

Creeping eruption caused by nonhuman hookworm larvae usually involves one or two species of cat and dog hookworms — *A. braziliense* and *A.*

patients. Real, although limited, insight can be gained, elementary interpretations accepted and synthesized, anxiety reduced, and a program of living that involves a minimum of interpersonal conflicts adopted within the time limitations of the therapy provided in the clinic. Although the patient may not be completely well, he can be taught to recognize the sources of his difficulties and given technics for avoiding most of the larger collisions. Our aim, then, may be summarized by an analogy from the field of physical medicine: when we cannot cure the disease, we try to provide an adequate form of compensation. It is our hope that our compensated neurotic patients may, like compensated cardiac patients, lead successful and satisfying lives, although more restricted than those of normal persons.

SUMMARY

A description is presented of the location, staff, admission policy, clinic procedures, staff training program, therapeutic goals, types of treatment given and results of the Veterans Administration Mental Hygiene Clinic in Boston at the close of its first three months of operation.

Individual psychotherapy is the method of choice, but group therapy plays an important role in the treatment program. The type of group therapy utilized is briefly described.

Analysis of the progress of 228 patients shows that approximately 15 per cent were discharged, that the treatment in 28 per cent had lapsed and that 55 per cent were undergoing active treatment.

CREEPING ERUPTION IN NEW ENGLAND*

A Report of Two Cases

CHARLES U. LOWE, M.D.,† AND DONALD L. AUGUSTINE, Sc.D.‡

BOSTON

ONE of the cases of creeping eruption reported below was attributed to the dog hookworm, *Ancylostoma caninum*, and was actually acquired in Boston. Although frequent enough in tropical and subtropical countries, this infection has been reported only once before in New England, in a patient who became ill in Florida.¹ The clinic to which the patient in Case 1 reported would probably have been confounded by his skin lesion had he not brought with him a note from a physician in Louisiana who had made the proper diagnosis. The patient in Case 2 had previously suffered from creeping eruption, and the appearance of the lesion was known to his mother, so that the problem of initial diagnosis was not present. Since this peculiar lesion may occur oftener in New England, this report should aid in its immediate recognition.

CASE 1 (C. H. 308407) R. V., a 2½-year-old boy, was first seen on August 13, 1946, in the Medical Out-Patient Department of the Children's Hospital, because of a localized skin lesion. Accompanying him was a note from the Station Hospital at Camp Pope, Louisiana, stating that the patient had been treated on August 1 with ethyl chloride because of "hookworm infection of the left foot." The social and past histories were noncontributory.

The patient had been well until July 28, when he was living with his mother and father, a lieutenant in the Army, at Camp Pope. He had been permitted to play outdoors unrestrictedly and had frequently been observed playing

without his shoes. On July 28 the mother first noted a large red papule on the left foot between the first and second toes. This was evidently pruritic and kept the patient awake at night. Two days later the lesion had become about 12 cm. long and described a circinate course over the dorsum of the foot. On August 1 the patient was seen at the camp hospital, and a diagnosis of "hookworm disease of the skin" was made. Local ethyl chloride therapy was instituted. Subsequently, a moderately severe slough resulted. Penicillin ointment was applied over the lesion, which healed without complications. On August 3 the family departed for Boston, where they took up residence with the maternal grandparents. Four days later the mother noted two new papules, one over the left tibia and one on the flexor surface of the right forearm. On August 12 the papules had changed to circinate lesions 2 to 3 cm. long. Pruritus again became troublesome, and the child was unable to sleep at night. Because of this, medical advice was sought.

Physical examination revealed an apparently well developed and well nourished child who was in no distress except for the itching skin lesions. On the left instep an area of new epidermis, 8 by 12 cm. in diameter, was visible. This was healing well. On the flexor surface of the left forearm and over the left tibia were single 4-cm. long, irregular, raised, serpentine lesions 2 mm. wide and surrounded by evidence of recent excoriation. Occasional vesicles, 2 mm. in diameter, were present on either side of the burrows. The rest of the physical examination was of no consequence. Since a consultation with the Department of Tropical Medicine, Harvard Medical School, could not be obtained until August 17 the mother was instructed to treat the lesions with calamine lotion in an attempt to control the itching, and to return for consultation.

On August 17 a new eruption had appeared on the left biceps within the previous 24 hours. This lesion was similar to those previously noted. Consultation confirmed the diagnosis of creeping eruption, and therapy with carbon dioxide snow was advised. Three days later examination of the blood disclosed a red-cell count of 3,800,000, with a hemoglobin of 74 per cent (10.5 gm.) and a white-cell count of 10,300, with 39 per cent neutrophils, 50 per cent lymphocytes, 3 per cent monocytes and 8 per cent eosinophils. Examination of the patient's stools on two occasions was negative for intestinal parasites.

man. Two naturally acquired infections with the former are recorded from the Philippine Islands,⁹ and a third infection has been reported in a boy in Texas.⁷ It therefore appears that man is highly resistant to infection with *A. caninum* and that the infective larvae of this species seldom leave the dermal tissues, where they are effectively destroyed. *A. braziliense*, which is more successful as a human intestinal parasite, is a relatively frequent intestinal parasite of man throughout the Orient and is rare in the Amazon Valley, Brazil.¹⁰ Only one such infection has been noted in the United States.⁷ This occurred in the same boy in Texas who was also infected with *A. caninum* and *Necator americanus*. Individual infections have always been light.

The relative frequency of human intestinal infection with *A. braziliense* in the Orient and its apparent absence in the Western Hemisphere have suggested a duality of types — that is, an oriental type, which has become better adapted to the human host, and an occidental type, which is merely in the first stage of adaptation. The fact that creeping eruption, the manifestation of host resistance, is common in the southeastern states where human intestinal infection with this hookworm is virtually unknown, and the absence of creeping eruption and the rather frequent intestinal infections with *A. braziliense* in the Philippine Islands, as reported by Africa,¹¹ support the view that two distinct types of this species exist.

Creeping eruption is relatively rare among Negroes. Dove⁷ reported that of 301 cases of creeping eruption at Jacksonville, Florida, only 5 (1.6 per cent) occurred in Negroes. There is also a marked racial difference in the incidence and intensity of hookworm infection (*N. americanus*). In endemic areas and when living under almost identical conditions of sanitation, economic status, occupation, soil, temperature and rainfall, the Whites characteristically have a heavy hookworm infection whereas the Negroes have a light one.¹² There is no explanation of this fact, but it is believed to be due to a physiologic difference in the two races — namely, the much greater thickness of the epidermis of the Negro, which provides a natural barrier against infective hookworm larvae.

In view of the fact that *A. caninum* is a relatively frequent parasite of dogs in New England, the question arises concerning the reason for the rarity of creeping eruption in the human population. *A. caninum* occurs most frequently in New England kennels. The infection is rare in stray and vagrant dogs, but is a characteristic infection of puppies. Well-nourished adult dogs are highly resistant to hookworms.¹³ Puppyhood is of relatively short duration and the hookworms acquired in a kennel are self-eliminated as the dog matures. Accurate data are not available, but it is highly probable that for most New England farm dogs and house pets harboring hookworms, the infections are light. The lack of a sufficient number of consecutive days

with favorable temperature and moisture for larval growth of the parasite in New England soil, together with light hookworm infections in the dogs, does not permit the development of a heavy soil infection under most circumstances. Only in kennels and under unusual conditions, such as those in Case 2, are soil infections likely to become sufficiently heavy and concentrated to cause creeping eruption. The apparent absence of creeping eruption among kennel owners and workers in New England may be attributed to the wearing of footgear which adequately protects the skin against immediate contact with hookworm larvae in the soil.

Thus far the most satisfactory treatment for creeping eruption is local freezing applied to the skin in the advancing area of the lesion. Either carbon dioxide snow or ethyl chloride spraying may be used.¹⁴ Fuadin (antimony biscatechol disulfonate of sodium) has been tried with variable success.^{15,16} A yearly fecal examination of pet dogs and cats, with anthelmintic treatment to those found positive for hookworms, would provide a practical precautionary measure.

SUMMARY

Two cases of creeping eruption are reported, one of which was certainly caused by *Ancylostoma caninum* of canine origin and was acquired in Boston. The second case, acquired in Georgia and observed in Boston, was probably caused by *Ancylostoma braziliense*. A review of the literature failed to reveal any other case of creeping eruption due to a hookworm larvae acquired in Massachusetts.

Factors probably responsible for the rarity of creeping eruption in New England are considered.

caninum Whereas both species are frequent intestinal parasites of both hosts, *A. braziliense* occurs oftener in cats and *A. caninum* occurs more frequently in dogs. Both are world wide in distribution, *A. braziliense*, which is widely established in tropical and subtropical countries, is not normally found in North America as far north as Baltimore.² Although *A. caninum* is likewise widely distributed throughout the warm countries, it differs from *A. braziliense* in that its range extends well into temperate climates. It is a frequent and important parasite of dogs in New England.

The first accurate knowledge of the life history of hookworms was gained from the experimental studies with *A. caninum* by Looss³ in 1911. Eggs, which are the product of the adult male and female worms in the intestine, are deposited on the soil with the feces of the infected host. Development of the embryo is rapid, and hatching occurs in about twenty-four hours. The young hookworm larva, which feeds on bacteria in its environment, reaches its third stage of development — the infective stage — within about five days. Favorable temperature, moisture and type of soil are primary requisites for this development.^{4,5} Having reached the infective stage, the larva no longer feeds during its free existence, its main function is to carry the species to a new host. In moist soil it remains extended from the uppermost soil particles, singly or in large aggregates, within the immediate area of soil pollution.⁶ When these infective larvae, which are markedly thermotropic, are transferred to the skin of warm-blooded animals, activity is greatly aroused, and almost immediately the larvae begin boring into the tissues. Once within the proper host, the infective larvae quickly leave the dermal tissues, enter the lymphatic vessels, and after a circuitous migration, arrive in the small intestine, where they become adult male and female worms.

When infective hookworm larvae invade the skin of a foreign or refractory host, they frequently fail to leave the dermal tissues, through which they burrow indefinitely, producing indurated, sinuous tunnels that progress at the rate of several millimeters to a few centimeters each day. Without intervention, such larvae may continue their migration for weeks or months. This behavior is characteristic of cat and dog hookworm larvae attempting to infect the human body.

A stinging, prickling sensation may be experienced at the time the larvae invade the skin. The first visible lesions — maculas and papules — usually appear after the second or third day of infection, tunnel formation beginning on or after the fourth day of infection. As the advancing end of the line progresses, the opposite end fades away.

Differences have been noted in experimental infections in the type of lesion caused by *A. braziliense* and *A. caninum*.⁷ The lesions caused by the former are characteristically continuous with the points

of entry of the larvae, whereas those of the latter may be discontinuous, apparently because these larvae penetrate the deeper tissues and later return to the surface of the skin at some distance from the point of entry. Marked variations have also been noted in different persons following experimental or accidental infection with a known species.⁸ Therefore, it is not possible to make a specific diagnosis on the character of the lesion or to identify the species on larvae excised from a lesion. The most helpful definitive differential diagnostic method is the isolation of adult hookworms from the small intestine of the animal presumably responsible for the human infection. The diagnosis of *A. caninum* infection was made in Case 1 by means of this procedure.

The fact that new lesions in Case 1 appeared two weeks after the patient arrived in Boston clearly suggested that these last lesions had been acquired locally and that the source of infection was nearby. On questioning, it was learned that the family pet was a five-and-a-half-month-old cocker spaniel that had been acquired in Louisiana and had accompanied the family to Boston. A stool from the dog was examined on August 19 and found to be positive for hookworm eggs. On the request of the mother, the dog was sacrificed at the Angell Memorial Hospital. At autopsy, twenty-two male and thirty-four female *A. caninum* were removed from the small intestine. Since this dog appeared to be the only source of infection, it was concluded that the lesions in this patient were caused by that organism. No specific diagnosis was possible in Case 2. Since, however, cats, but not dogs, were on the premises in Savannah, it is likely that the causative agent was *A. braziliense*.

To complete the study of the patient in Case 1, soil samples were taken from around the house of the family to determine areas of soil infection. This house, typical of many in eastern cities, had a small enclosed back yard, which limited the excursions of both the boy and the dog. Most of the enclosure was so overgrown with bushes and tall grass that the boy's play yard was largely restricted to a small area under a rear porch and its steps, which was also the habitual place in which the dog defecated. Almost continuous rains since the arrival of the family in Boston rendered this particular spot ideal for the development of hookworm larvae.^{4,6} On completion of selection of soil samples, it was learned that the mother had flooded the area with boiling water the day the dog had been sacrificed. No hookworm larvae were found in any of the soil samples. Since no new lesions have been acquired, it appears that the use of boiling water had effectively destroyed any hookworm larvae in the area.

Despite the common occurrence of creeping eruption in certain parts of the world, *A. caninum* and *A. braziliense* seldom cause intestinal parasitism in

and upper two lumbar vertebrae without dividing the muscle. Otherwise, the extent of the operation remained unchanged — that is, removal of sympathetic trunks from the eighth thoracic to the first or second lumbar ganglion, inclusive, and of the great splanchnic nerves from the celiac ganglions to the midthoracic level. Poppen⁹ removed a segment of the tenth or eleventh rib, instead of the eleventh and twelfth, and obtained a lumbar exposure below the twelfth rib, working above and below the diaphragm without dividing the latter. The extent of the removal of the sympathetic trunks and splanchnic nerves is from the seventh or eighth thoracic segment to the second or third lumbar ganglion. More recently, Hinton and Lord¹⁰ suggested a variation in which a segment of the ninth or tenth rib is removed, the diaphragm is divided transversely from above and the sympathetic trunks, together with the splanchnic nerves, are removed as a rule from the third or fourth thoracic segment to the second lumbar ganglion inclusive. The operation is carried out either extrapleurally or transpleurally. They correctly point out that this operation is of greater magnitude and more serious for the patient, and that it is entirely conjectural whether the late results will show any greater benefit. If my concept of the origin of the vasoconstrictor nerves to the splanchnic bed is correct, it does not seem likely that these more extensive procedures will result in a more thorough denervation of this area. From my point of view, the most logical reason for extending this operation is to include the cardiac innervation, which the variations mentioned above do not accomplish. In a number of failures following lumbodorsal splanchnicectomy I have extended the operation subsequently to total sympathectomy to include the heart, so far without notable success. It is possible, however, that in certain cases cardiac denervation should be a part of the original maneuver. It is believed that lumbodorsal splanchnicectomy as described^{5, 11, 12} is the procedure of choice in the great majority of selected cases of continued hypertension because it offers a 75 to 85 per cent chance for improvement at an operative risk of less than 1 per cent.¹²

Results of Surgical Treatment

Peet¹⁴ has recently discussed the late results in a series of 437 cases operated on by his supradiaphragmatic technic. The patients had been followed for five to eleven years. In 82 per cent serious organic disease was demonstrable prior to operation. Two hundred and fifty-one, or 57.5 per cent, were alive at the time of follow-up study.

Of patients with symptoms and fundus changes but without cerebral, cardiac or renal involvement, 95 per cent were living five to eleven years after operation. These represented 17 per cent of the total series. Of these, 30 per cent had normal blood

pressures, and another 47 per cent had maintained significant reductions. Symptoms had been completely relieved or definitely improved. Angiospastic retinal changes had been improved in a remarkably high percentage of cases. Normal electrocardiograms, heart size and kidney function had been adequately protected. Approximately a third of all the patients who showed preoperative evidence of organic heart disease, cerebrovascular disease or impaired kidney function did not survive five to eleven years. Half the patients who fell into these categories maintained significant blood-pressure reductions for the same period of observation. Symptomatic improvement occurred in a high percentage, apparently being present in as many of this group as in the most favorable cases mentioned above. Sixty per cent of patients who had suffered a cerebral accident had no recurrence of this complication after splanchnicectomy.

Of the cases with malignant hypertension, 19 per cent were alive five to eleven years after operation. These patients had severe neuroretinitis with papilledema of 1 diopter or more prior to operation. The usual mortality for such cases prior to the advent of surgery was approximately 80 per cent within one year, 90 per cent within two years and 99 per cent within five years.¹⁵

Experiences with lumbodorsal splanchnicectomy in the treatment of hypertension and hypertensive cardiovascular disease have been discussed by Ayman and Goldshine,¹⁶ de Takats, Heyer and Keeton,^{17, 18} Hinton and Lord,¹⁹ Ray,²⁰ and Smithwick^{11-13, 21, 22} and in numerous communications by White et al.²³⁻³⁰ These authors appear to be in agreement that surgery is a useful adjunct in the management of the hypertensive patient. White et al. have emphasized the favorable changes observed in the hypertensive heart, particularly improvement as demonstrated in the electrocardiograms and heart size and function. Favorable changes also occur in eyegrounds and in renal function as judged by ordinary tests, as well as symptomatic improvement. The early indications are that life expectancy will be materially improved.

Selection of Patients for Surgery

In a recent review of the results of lumbodorsal splanchnicectomy in a series of 439 cases followed for one to eight years, the selection of patients for surgical treatment is discussed in considerable detail.¹² A standard method of study is described that was designed to obtain similar data in all cases and thus to subdivide patients into more comparable categories. All the cases in this series had reached the stage of continued hypertension, and 97 per cent had demonstrable cardiovascular damage prior to operation. These were an unselected group of patients. Over 60 per cent were improved when judged by both blood-pressure data and favorable changes in cardiovascular damage. These results

MEDICAL PROGRESS

SURGERY OF THE AUTONOMIC NERVOUS SYSTEM

REGINALD H. SMITHWICK, M.D.*

BOSTON

THE following phases of the surgery of the autonomic nervous system will be considered: operations on the sympathetic division, the pathologic and physiologic aspects of the hypertensive state, and operations on the parasympathetic division.

OPERATIONS ON THE SYMPATHETIC DIVISION

The treatment of hypertension and hypertensive cardiovascular disease by operations on the sympathetic division of the autonomic nervous system continues to be the topic of greatest current interest in this field of surgery. The rationale was well stated by Rowntree and Adson¹ in 1925 in what appears to be one of the first articles on this subject. The authors discussed their experiences with 2 patients treated, respectively, by periarterial sympathectomy of the left femoral artery and lumbar sympathectomy. Since the treatment of a great many patients with malignant hypertension had ultimately been disappointing, it occurred to Rowntree and Adson that relative freedom from vascular spasm might be attained through the removal of the vasoconstrictor influence of the sympathetic nerves on the vessels of the leg. It was thought that this might not only lower the systemic blood pressure but also provide simultaneously an area of diminished resistance that would give way under strain and thereby serve somewhat in the capacity of a safety valve for the protection of the cerebral and retinal vessels. In other words, it was their concept that sympathectomy might decrease the peripheral resistance to blood flow and thus result in a lowering of the blood-pressure levels. Also, fluctuations of blood pressure might be minimized, the intermittent stress and strain on the vascular bed being thereby reduced. Although over twenty years have passed since this original attempt to modify the course of hypertensive cardiovascular disease by therapy of this sort and although various suggestions have been made to account for favorable results, no likelier explanation has been advanced to date. Proof of the nature of the effect must await detailed physiologic studies before and after operation. These, unfortunately, have not as yet been carried out in sufficient detail to be conclusive. Discussion so far has therefore centered about objective evidence, such as changes in blood pressure

or the reversal of cardiovascular damage that existed prior to operation.

Extent of Operation

Because periarterial sympathectomy and lumbar sympathectomy had little effect on blood pressure, Adson,² in 1930, extended the operation to include the splanchnic bed. A laminectomy was performed, and the anterior roots were sectioned bilaterally from the sixth thoracic to the second lumbar segment, inclusive. This operation was much more effective but had to be abandoned because of the high mortality and morbidity. Alternate procedures were developed in fairly rapid succession, including the subdiaphragmatic technic of Craig³ in 1934, the supradiaphragmatic splanchnicectomy of Peet⁴ in 1935 and the lumbodorsal or thoracolumbar splanchnicectomy of Smithwick⁵ in 1940. These operations have a similar purpose—namely, to denervate a large vascular area (the splanchnic bed) that contains a large portion of the arterioles of the body. It is generally believed that in hypertensive patients, the increased peripheral resistance to blood flow is offered by vessels of this size. The operative mortality has been low. In 1941 Grimson⁶ suggested that total thoracic or total sympathectomy might be more effective. The purpose of these more extensive procedures was to include the heart in the denervated area. Grimson was led to believe that this was indicated as a result of his experiences with dogs in which experimental neurogenic hypertension could not be significantly modified unless the heart was included in the denervated area. As might have been expected, the mortality of these more extensive procedures was considerably higher than that of the various forms of splanchnic denervation mentioned above. The percentage of successes in unselected cases seemed not appreciably higher than that for the lumbodorsal technic, although it should be stated that Grimson's series was not large enough to be fairly evaluated at that time. Further reports will be awaited with interest. In a recent review Grimson⁷ expressed the opinion that clinical experience with the treatment of hypertension indicated that elimination of abnormal reflex vasoconstrictor tone of central origin more effectively reduces blood pressure as sympathectomy of the body is made more and more complete.

In the recent literature a number of articles have appeared describing modifications of the lumbodorsal technic. Klemme and Woolsey⁸ separated the diaphragm from the bodies of the twelfth dorsal

*Professor of surgery, Boston University School of Medicine; surgeon-in-chief, Massachusetts Memorial Hospitals; member, Board of Consultation, Massachusetts General Hospital.

to this school of thought. Physiologic studies particularly renal-clearance observations by Smith⁴¹ abundantly corroborated by others,⁴² have together with biopsy material,^{43, 44} cast considerable doubt on the primacy of renal arteriolar disease as the usual causative mechanism. The evidence has been reviewed in some detail, the essential conclusions being that data pertaining to the gross appearance of the kidneys, accumulated during the course of the surgical treatment of hypertensive patients indicate clearly that contracted granular kidneys do not antedate the hypertensive state in man. The following conclusions are drawn^{45, 46}

For the first time, an opportunity for the microscopic study of renal arterioles of living patients with continued hypertension has presented itself. The findings are also at variance with autopsy material. They suggest that pre-existing renal arteriolar disease of a moderate or marked degree is not a *sine qua non* to the hypertensive state.

For the first time, an opportunity has arisen whereby the pathological changes can be correlated with the physiological state of the kidney. It has been noted that neither a marked reduction in quantity (ischemia) nor a change in the nature of renal blood flow (constriction of the efferent glomerular arterioles) is obligatory to the hypertensive state.

When renal vascular disease and hypertension are associated, it is difficult to disprove a cause and effect relation, and no one questions the importance of renal disease when present, as a factor in human hypertension. However, to make this the universal explanation for hypertension in man is not in keeping with the facts. A concept is needed, which will explain the cause of hypertension in the absence of kidney disease, and the absence of hypertension in the presence of kidney disease.

The surgical treatment of hypertension has introduced a new factor, the autonomic nervous system, into the already complicated picture of the hypertensive state in man. It has contributed data which cast doubt upon the primacy of renal arteriolar disease as the sole causative factor.

It is most desirable that the explanation for reduction of blood pressure following splanchnicectomy be determined, since this may lead to a clearer understanding of causative mechanism. It might also lead to the development of accurate methods of selecting cases for this form of treatment. It might indicate productive lines for future investigative work. More detailed studies of the cardiovascular system in hypertensive patients are obviously indicated and may yield information of great value that cannot necessarily be obtained in the experimental laboratory. Collaborative efforts of physiologists, pharmacologists, biochemists and clinicians are needed to accomplish this purpose. Already, a beginning has been made in this direction, and important evidence is being accumulated as a result of such studies. Talbott et al⁴⁴ measured the blood flow through the renal area before and after lumbodorsal splanchnicectomy in a series of 20 cases. Prior to operation a wide variation was noted — from normal levels to a marked reduction. The authors were unable to detect any significant alteration in renal blood flow after operation regardless of the effect on the blood pressure. Further studies of this sort are indicated. More recently, Stewart et al⁴⁷ studied the part of the volume out-

put of blood from the heart that is allotted to the peripheral circulation. These observations were made in normal subjects and in patients with hypertension. A trend toward a decrease in peripheral blood flow was found when there was hypertension, with a rise in the rectal and a decrease in the average weighted skin temperature. The temperature of the upper part of the body was warmer and that of the lower part cooler in hypertensive subjects than in those in the same age groups with normal blood pressures. The reduction in peripheral blood flow to the lower part of the body is greater than the increase in the upper part of the body so that the net result is an average peripheral blood flow for the whole body in hypertensive subjects that is less than the value in normal young men at the same room temperature.

Stewart et al⁴⁸ studied the peripheral blood flow in a series of hypertensive patients before and after splanchnicectomy by various techniques. They found lumbodorsal splanchnicectomy to have the greatest effect on the blood pressure. Following this operation, the blood flow in the upper portion of the body, which tended to be increased in hypertensive patients prior to operation, consistently fell somewhat. In the trunk and lower portion of the body where the tendency in untreated hypertensive patients was toward a decrease, the blood flow remained the same or increased. An increase in blood flow was consistently noted in the distal portion of the lower extremity. The over-all amount of blood allotted to the periphery in hypertensive patients in whom the blood pressure fell to normal after operation increased in some patients and decreased in others. The change was not statistically significant. In another group of patients in whom there was no lowering of blood pressure following operation, the change in peripheral blood flow was not significantly different from that in the group mentioned above. These findings are similar to those of Talbott et al⁴⁴ and others^{49, 50} regarding blood flow through the renal area before and after splanchnicectomy, there being no obvious relation between blood flow and blood pressure. Stewart et al⁴⁸ reached a similar conclusion concerning peripheral blood flow. "The level of blood pressure has no relation to peripheral blood flow either where the blood pressure is high or in the same patient after restoration of normal blood pressure." This viewpoint is of interest and of importance since it is not in keeping with the concept that hypertension is essential to the maintenance of adequate circulation to the tissues that is held by those who believe that elevated blood pressure results from vascular disease and is a compensatory mechanism. It is in keeping with clinical experience indicating that lowering of blood pressure by splanchnicectomy is helpful, not harmful, in the majority of hypertensive patients and is attended by improvement in the state of the cardiovascular system as judged by

were carefully studied, and certain rules were discussed by means of which the patients who had done poorly and those who had the smallest statistical chance for a worth-while result could be excluded with reasonable certainty. The suggested rules apply to about 30 per cent of patients with continued hypertension and cardiovascular changes, leaving 70 per cent that could be regarded as selected cases. In these, there was a 75 to 85 per cent chance for a favorable effect on both the blood pressure and the cardiovascular system following operation. In addition, 113 per cent showed no progression. The total mortality from all causes, including operative mortality and deaths unrelated to the disorder in question, for the follow-up period of one to eight years was remarkably low, 98.8 per cent of the patients being alive at the time the analysis was made. This series comprised many cases with previous cerebrovascular accidents, abnormal electrocardiograms and enlarged hearts and some with congestive failure or previous coronary thromboses, as well as definite evidence of renal disease as judged both by tests of function and by the study of biopsy material obtained at operation. It is expected that a larger experience and a longer follow-up period will suggest further rules designed to improve accuracy in the selection of cases for this form of treatment. Because of the amount of data that have been obtained in the study of each case, it is expected that when the series is larger it will be possible to divide the cases into many smaller groups, so that almost any hypertensive patient will fall into one of them. The effect of surgery of this sort on blood pressure, the cardiovascular system and life expectancy can then be foretold accurately. Such variables as sex, age and the severity of the hypertension — as judged by the resting horizontal diastolic level, the width of the pulse pressure and the state of the brain, eyegrounds, heart and kidneys, as well as the response to sedation and other transient methods of inactivating sympathetic activity — will have to be held constant in each subgroup. One of the great difficulties about any discussion of the results of surgical treatment of hypertensive patients at present is the fact that no such comparable data for nonsurgically treated patients are available for comparison. Consequently, these results are open to as much criticism as anyone wishes to level at them. In any event nobody questions the facts that the complications of hypertension are responsible for more deaths annually than any other human disorder and that a reduction of this mortality rate and an increase in the life expectancy of this group of patients are highly desirable. To meet the objection mentioned above the natural course of a control series of similarly studied patients who have not as yet been subjected to surgery is being followed. It is essential that the method of study be comparable in every respect. It would not be proper,

for example, to compare patients with transient or intermittent hypertension with those who have passed through this phase and have reached the stage of continued hypertension in which the diastolic pressure no longer falls to normal after a period of bed rest. Nor would it be proper to compare cases of continued hypertension without cardiovascular changes with those having damaged vascular beds. The latter is the group with which I have been primarily concerned to date. If a simple panacea for this disorder is ever discovered, it will undoubtedly be found to be most effective if employed before the vascular bed is damaged. The same thing will probably be true of surgical treatment. Earlier operation has been suggested by White,²⁹ Landis³¹ and de Takats.¹⁸

In the recent literature the use of spinal anesthesia by one technic or another has been advocated as a means of selecting cases for surgical treatment.^{22, 23} The data so far presented do not appear to be significant. Also, the effect of newer sympatholytic drugs has been described.^{34, 35} It seems unlikely that any diagnostic procedure that has a transient effect will be the entire answer to this difficult problem. There may be an adequate correlation in patients who respond well to those temporary measures and the effect of operation. There will probably be an unsatisfactory correlation in those who do not respond well to tests but who do benefit by surgery. The matter appears to me to be a little too complex to be amenable to solution in this fashion. It also seems likely that at least a part of the favorable effect of sympathectomy cannot be measured by changes in blood-pressure levels alone.

PATHOLOGICAL AND PHYSIOLOGIC ASPECTS OF THE HYPERTENSIVE STATE

Although the primary purpose of the surgical treatment of these patients has been to lessen the severity of the hypertension, to reverse cardiovascular changes when possible and to increase life expectancy, it has been realized that this approach to the problem has offered a unique opportunity to obtain factual data concerning the pathologic physiology of the hypertensive state. In particular, it has been possible to visualize the kidneys at operation and to obtain specimens for microscopical study. Ever since Richard Bright^{36, 37} first called attention to the entity of hypertension and the role of the kidney in the production of increased tension within the vascular bed, opinions have varied concerning the importance of the renal vascular area in the genesis of this disorder. The demonstration by Goldblatt³⁸ that reduction of blood flow through this area by clamping of the renal arteries resulted in chronic hypertension in animals has further stimulated interest in this matter. The detailed studies of Moritz and Oldt,³⁹ notwithstanding the discussion of this matter in 1872 by Gull and Sutton,⁴⁰ added further impetus

other stimuli, particularly some of an emotional variety, may cause increased vagal activity and acid secretion. There is no reason to doubt that the secretory response to these stimuli is inhibited by vagectomy. Thus, an over-all effect of this operation is to reduce both continuous and intermittent gastric secretion of neurogenic origin. Its efficacy in the treatment of some duodenal ulcers may depend on the extent to which the first period of gastric secretion, the cephalic phase of the second period, and other neurogenic or psychosomatic mechanisms enter into the problem at hand. It is true, however, that in other ulcer patients there is little evidence of an abnormality of neurogenic secretory mechanisms. Whether there will be any great effect on either the gastric or the intestinal phase of the secretory process awaits further study. These are thought to be largely under the control of chemical substances of a histamine-like nature. After vagectomy, a response to histamine or caffeine still persists, although in some cases a reduction has been noted following histamine, as pointed out by Grimson.⁵⁵ The explanation for the latter is not clear.

In addition to these reported changes in gastric secretion, an alteration of gastric and intestinal motility is noted, particularly in the immediate postoperative period. This is evidenced by a delay in the initial as well as the total emptying time of the stomach. Its tone and reactivity are likewise decreased. These changes become less marked in the course of months and are rarely attended by symptoms of consequence. Whether these motility changes have any beneficial effect on the healing of peptic ulceration is not known.

Grimson⁵⁵ believes that although changes in secretion and acidity are important, the most pronounced and consistent change produced by vagectomy is the decrease in motility of the stomach. On the other hand, Dragstedt⁵⁴ points out that in experimental animals in which gastric juice is allowed to be in contact with the intestinal mucosa when the alkaline duodenal secretion has been shunted distally (as in Mann-Williamson dogs) ulcers regularly develop. In these animals the motility factor has probably not been materially altered. In almost all reported cases the relief of symptoms, particularly pain, has been dramatic, immediate and persistent. Nearly all ulcers have healed promptly. The effect of operation has so far been particularly gratifying in the group of troublesome cases in which gastrojejunal ulcerations have developed following gastric resections. The relief from pain is of interest since it is not associated with evidence that pain pathways have been divided as judged by postoperative balloon-distention observations. Pain is still perceived in response to stimulation of the esophagus, duodenum and jejunum⁵⁵ and when hydrochloric acid is introduced into the stomach.⁵⁵ It therefore appears that relief is more probably due to decreased acidity or motility or to both.

Surgical Technique

An excellent review of experimental work in this field and of the earlier attempts to perform an effective interruption of the vagal innervation of the stomach in man was recently published by Weinstein et al.⁶⁰ Partial division of the vagal fibers to the stomach by vagotomy for the relief of peptic ulcer was performed by Suerlin in 1920, Bircher in 1921 and Schiassi in 1925. In 1937 Barron and Curtis divided the left (anterior) vagus nerve in a case of gastric hypertonia. Winkelstein and Berg⁶¹ combined anterior vagotomy with subtotal gastrectomy for duodenal ulcer in patients with high gastric acidity in 1938. In all these operations, an abdominal approach was used. The denervation was only partial.

To study the relative merits of partial and total parasympathetic denervation of the stomach Weinstein et al.⁶⁰ studied the behavior of three types of gastric pouch in dogs: the Heidenhain pouch, which receives no vagus innervation, the Pavlov pouch, in which only a small percentage of vagal fibers remains intact, and the so-called "vagal" pouch, in which practically all the vagal fibers are unsevered. The secretory responses to the ingestion of food, as measured by the acidity curve, were found to be essentially the same in all varieties of pouches. When, however, a stimulus was applied that operated through the nervous system, good secretory responses were noted in the totally and partially innervated pouches, being equally marked in each. This is an important observation, since it confirms a general law that has been previously learned in surgery of the sympathetic nervous system — namely, that a denervation must be complete to be effective. In only the Heidenhain pouches (totally denervated) was there no secretory response to this stimulus. Weinstein et al. believe the insulin test to be an effective indicator of the completeness of denervation following vagectomy in man. It is performed on a fasting stomach with a tube in place. The contents are aspirated, and 15 units of regular insulin is injected intravenously. Following this, gastric specimens are withdrawn every fifteen minutes for three hours, and blood sugar determinations are made at the beginning of the test and every half hour for one and a half hours. In 6 cases in which various types of vagectomies and vagotomies were performed, evidence of incomplete denervation was found after operation as judged by a significant acid secretory response to insulin. This led the authors to conclude that complete parasympathetic denervation of the stomach was impractical in man. Dragstedt et al.⁵⁴ and Moore and his associates⁵⁵ found the postoperative response to insulin to be abolished. Grimson⁵⁶ reported a variable reduction. My own experiences indicate that vagectomy has so far been uniformly successful in abolishing or greatly reducing postoperative

favorable changes in the cerebral, retinal, cardiac and renal areas, as well as in symptoms. Stewart et al also noted that the rectal temperature, which was elevated in hypertensive patients, fell after operation. Also, in patients who experienced a fall in blood pressure to normal there was a decrease in the mean basal metabolic rate. In patients in whom there was no change in blood pressure there was no change in the basal metabolic rate. Studies of this sort are significant, representing the beginning of what must be determined to explain the mechanism whereby blood pressure is lowered following surgery. The crucial questions are whether sympathectomy lowers blood pressure by affecting active causative mechanisms of a physiologic nature, or whether the effect is due to a change in hemodynamics that counteracts hypertension. Why does splanchnicectomy fail to affect hypertension in certain cases? The correct answer to these questions may have an important bearing on the cause of hypertension in man.

OPERATIONS ON THE PARASYMPATHETIC DIVISION

With the exception of sporadic attempts to relieve bronchial asthma by resection of vagal fibers to the lung, little has been attempted in the way of surgery of the parasympathetic nervous system. In recent years reports of experiences with resection of the vagus nerves to the stomach in the treatment of peptic ulcer have appeared in the literature. The early results seem encouraging and suggest that vagectomy may prove to be a useful adjunct to other measures available for the management of this disorder. A widespread interest has developed, and it is to be expected that the possibilities of this therapeutic measure will be explored in many clinics and that the literature on this subject will increase considerably in the next few years. As with everything that is new, the test of time will have to be applied before a final evaluation of results can be made.

Perhaps it is not quite correct to refer to vagectomy as a new procedure. Physiologists have been familiar with it for many years and have studied its effect on gastric function in great detail. One of the earliest references to its application in man is a report by Pieri⁵¹ in 1932. He performed bilateral subdiaphragmatic resection of the vagus nerves in 14 patients for the relief of gastric disorders, and stated that the operation was well tolerated and did not cause appreciable untoward incidents. The report that stimulated current interest in this matter was that of Dragstedt and Owens⁵² in 1943. Their first 2 patients were operated on in January and February of that year. Since that time additional reports of progress have been made by Dragstedt and his associates^{53, 54} Moore et al⁵⁵ and Grimson⁵⁶ have also reported early results.

Rationale of Vagotomy for Peptic Ulcer

In their writings to date, Dragstedt et al have stressed the use of vagectomy in cases of refractory and complicated ulcer. Most of their subjects have been men with long-standing duodenal ulcers with or without previous surgery. They have also stressed the effect of this operation on the first period of gastric secretion — namely, that of interdigestive or continuous secretion. To obtain data on this matter, they collected gastric juice for twelve-hour periods from 9:00 p.m. to 9:00 a.m. by continuous suction, the stomach having been emptied and washed out prior to the collection period. The average findings for at least three such periods of observation prior to operation in 10 patients with refractory ulcer who had had no previous surgery were as follows: volume, 821 cc, free acid, 47 units, and total acid, 66 units. Following operation, the corresponding values were 335 cc, 15 units and 46 units. In 9 cases of complicated ulcer the findings before and after vagectomy were similar. Some of these patients were obstructed, and a gastroenterostomy was also performed; others had had previous gastric resections or gastroenterostomies. In the discussion of the paper in which these results were reported, Grimson indicated that the twelve-hour night-secretion volumes in his series of 18 cases were reduced from an average of 946 cc before operation to one of 342 cc after operation. The acidity expressed in terms of pH was changed from an average of 1.72 before to 3.55 after vagectomy. These findings are of interest, not only because they indicate at least one clear-cut physiologic effect of the operation but also because they cast additional light on the explanation for the period of continuous gastric secretion. As recently as 1941 Ivy,⁵⁷ in an excellent discussion of the mechanisms of gastric secretion, indicated that the nature of the stimuli that give rise to the continuous secretion of gastric juice is uncertain. He stated that some patients, particularly those with a duodenal ulcer, manifested a hypernormal continuous secretion — that is, the stomachs continued to secrete a copious quantity of acid juice after emptying. He suggested that this might be due to the production of histamine by an irritated mucosa, since atropine in relatively large doses does not abolish abnormal continuous secretion whereas it has a significant effect on normal gastric secretion as shown by Keefer and Bloomfield.⁵⁸

In addition to the effect of vagectomy on the first period of gastric secretion, it seems probable that certain aspects of the second are favorably affected. This period may be divided into three phases: the cephalic, the gastric and the intestinal. The first is known to be under the control of the vagus nerves. Stimuli such as sight, smell, taste and thought of food result in gastric secretory activity mediated by the parasympathetic nervous system. Certain

insulin secretion as well as greatly modifying the volume and acidity during the continuous period of gastric secretion. Also, vagectomy has had a greater effect than preoperative atropine block on this period of gastric secretion. In some cases the response to histamine has been definitely reduced.

Successful bilateral vagectomy may be performed by either a transthoracic or an abdominal approach. In the former, an extensive resection of the seventh or eighth rib on the left side is advocated by Dragstedt and Schafer.⁵³ I have found this to give an excellent exposure of the operative field. The vagus nerves are quite readily exposed above the diaphragm and divided at this level. The various branches that form a network about the esophagus are gathered into two bundles and freed for about 10 cm above the diaphragm. The upper ends are sutured widely apart by Dragstedt, and the pleura closed. It has been my custom to encase the nerves in a silk cylinder as a further precaution against regeneration—a maneuver that has been used elsewhere⁶² in surgery of the autonomic nervous system. Moore et al.⁶³ have reported the use of this step in technic and in addition have divided the diaphragm and followed the branches of the vagi to their terminations in the stomach wall for additional protection against regeneration. So far, no definite evidence of this has been reported in the literature following supradiaphragmatic resection. A recent conversation with Dragstedt reveals that the patients in his earliest cases, who were operated on nearly four years ago, continue to do well.

The abdominal approach is useful when some additional procedure is indicated or when exploration of the lesion is considered advisable. In certain cases, particularly those with a high degree of obstruction combined with hypersecretion of the continuous variety, vagectomy has been combined with gastroenterostomy or gastric resection. If the left lobe of the liver is mobilized by division of its peritoneal attachment to the diaphragm, the esophagus is readily exposed. After its anterior peritoneal covering has been incised, dissection can be carried upward quite readily for about 6 cm above the diaphragm, and this portion of both the anterior and the posterior vagus nerves and their branches resected. In proper hands and under ideal circumstances it is apparent that these operations can be performed with an extremely low mortality and with few complications.

The Selection of Cases for Surgery

The writings of Dragstedt et al. have emphasized the significance of the first period of gastric secretion. They have indicated that hypersecretion has been present in the great majority of their patients. Their data suggest that the patients who exhibit this abnormality may be the ones who are likeliest to do poorly after subtotal gastrectomy. So far as the cephalic phase of gastric secretion is concerned,

it appears that studies of sham feeding have not revealed any conclusive evidence of abnormal responses in ulcer patients. Such reactions as exist should be modified by vagectomy. Moore et al. emphasize the importance of the history in ulcer patients, particularly evidence pertaining to the effect of stress and strain on symptoms. They regard young and middle-aged patients, who are most frequently men, with chronic ulcers that recur under stress and strain and are only transiently relieved by food or alkali as ideal subjects for operation. Previous perforation or hemorrhage is not considered a contraindication. Vagectomy should not be performed in their presence. The question of obstruction and its management by additional procedures such as gastroenterostomy and gastric resection remains for future evaluation. Because of increasing evidence pointing toward the danger of carcinoma in the presence of gastric ulceration, it appears inadvisable in general to treat cases of this sort by vagectomy. The early results of vagectomy are encouraging and warrant further study of its use in patients with duodenal ulcers requiring surgical treatment. It will be some time before the relative merits of and the indications for gastric resection and vagectomy are established.

The retrograde pyelogram shows good calyces, pelves and ureters on both sides

DR SHORT There is no definite evidence of pneumonia at the time of admission. We also have nothing to suggest any marked degree of pulmonary edema. The patient had no fever when she entered the hospital, which suggests that the infection, whatever it was, had cleared. The high white-cell count can probably be explained by a renal injury.

The next question and the chief one to answer is, What was the cause of the anuria and uremia that were evidently responsible for this woman's death? I am unable to decide from the evidence at hand that any of the usual forms of nephritis were present, although an acute glomerulonephritis secondary to infection could produce a clinical picture somewhat similar to this. The lack of fever is against a suppurative lesion of the kidney, and such rare conditions as dissecting aneurysm involving the renal arteries and renal infarction, I believe, we need mention only in passing.

I am forced to conclude that the renal shutdown was directly connected with the sulfonamide preparation taken by the patient. This preparation, I have been informed, contains 1.5 gm of sulfadiazine and an equal amount of sulfathiazole per 30 cc, with additional sodium citrate and sodium lactate in an aqueous solution, so that we do not need to worry about a toxic solvent's being involved. In the dosage given this patient received 6 gm of each drug, which does not seem excessive over two days, and we know that the solubility of the drugs was probably enhanced by the mixture of equal parts of each drug and by the additional alkali. For this reason, as well as the lack of severe pain, the absence of crystals in the urine and the negative findings on washing of the kidney pelves, I have decided against obstruction of the kidney pelves or the ureters by sulfonamide concretions as the cause of the anuria. These considerations do not rule out obstruction in the tubules themselves by sulfonamide crystals, but I prefer to believe that the anuria was due chiefly to a direct toxic action on the renal parenchyma. Such a process has been clearly described pathologically without evidence of obstruction by crystals, although it is less frequent as a cause of sulfonamide renal impairment than obstruction.

I might mention still another possibility that the renal damage was due to an acute hemolytic anemia resulting from sulfonamide administration. These cases occur nearly always with sulfanilamide, and we should expect jaundice and a severer degree of anemia to be present. As a matter of fact, if such an anemia had occurred, the pathological findings would have been closely similar to those that I expect to be found in this patient.

Before concluding, I should like to attempt to answer a few more questions. It would be interesting to know whether or not previous administration

of sulfonamides had taken place, so that the severity and the abruptness of the reaction could be explained on the basis of hypersensitivity. We are not helped by the history, and there were no other manifestations of sensitivity, such as fever and dermatitis. It is still possible that focal lesions in the heart and other organs will be found or even vascular changes resembling periarteritis nodosa, as described by Rich.^{1,2} But the short duration of administration of the drugs makes this unlikely unless the patient had previously been sensitized. Whether or not she had pre-existing renal disease that had made her especially susceptible to sulfonamide intoxication, I do not believe that we can find out, although the negative pyelogram helps rule out certain anomalies and diseases of the kidney. The site of damage in the group to which I think this patient belonged is usually the distal portion of the tubules, with involvement also of the interstitial tissue—so-called "lower-nephron nephrosis." A similar clinical picture can be produced by cortical necrosis. I have seen a reference to this condition that was presumably caused by sulfonamide intoxication,³ but I do not believe that we need consider it in the case under discussion.

In summary, I believe that the primary cause of death in this patient was uremia resulting from tubular necrosis caused by sulfonamides, with cardiac enlargement and arteriosclerosis as additional diagnoses. I do not believe that I can say anything about the changes in the lungs, unless edema developed before death. In a woman of this age other abnormalities or landmarks may well have been present, but I shall not try to predict what they were.

DR TRACY B. MALLORY Dr Dahl, will you tell us what the impression was on the ward?

DR LOUIS K. DAHL In general the house staff believed that the diagnosis rested between three main possibilities: acute glomerulonephritis, with sudden shutdown, interstitial nephritis due to sulfonamides, and—one person thought—bilateral cortical necrosis. The most prevalent opinion was interstitial nephritis caused by sulfonamides.

CLINICAL DIAGNOSIS

Interstitial nephritis, caused by sulfonamides

DR SHORT'S DIAGNOSES

Lower-nephron nephrosis, due to sulfonamide toxicity

Cardiac enlargement

Arteriosclerosis

ANATOMICAL DIAGNOSES

Periarteritis nodosa

Diffuse cortical necrosis, secondary

Arteriosclerosis

Hypertrophy of heart

Pulmonary emphysema

Cholelithiasis

CASE 33181

PRESENTATION OF CASE

An eighty-nine-year-old widow entered the hospital from a convalescent home because of oliguria.

The patient was unable to give a reliable history, and the only information that bore up under repeated questioning was that three weeks before hospital entry she had developed a cough productive of thick, yellow sputum and fever, nausea and abdominal soreness, with anorexia so severe that she took little food or water. Her physician disclosed that she had been given 120 cc of Aldiazol, a liquid sulfadiazine preparation, over a two-day period. Four days before entry the urinary output dropped markedly, so that only 180 cc of urine had been passed in the forty-eight hours before admission. The patient had previously noted darkening and reddening of the urine, but the volume seemed to have remained fairly normal. She denied backache and dysuria. Although she had eaten little during this time, she had drunk considerable fluid.

The past history revealed that she had had shortness of breath on exertion but no anginal pain. For several years she had taken digitalis irregularly. She had long been constipated and had used laxatives regularly for more than a year. She had never had any children, the ovaries having been removed many years previously for an unknown reason.

Physical examination revealed a moderately obese woman with a dry tongue. Although the memory was poor, she was alert and co-operative. The chest was emphysematous, with a moderate number of fine moist rales at both bases posteriorly. The area of cardiac dullness was obscured by emphysema. No murmurs were heard. There was slight tenderness in the right upper quadrant. The liver and spleen were not palpable. There was tenderness in both costovertebral angles, especially on the right. Pelvic examination revealed some tenderness on motion of the cervix upward. No masses were felt.

The temperature, pulse and respirations were normal. The blood pressure was 130 systolic, 65 diastolic.

Three cubic centimeters of dark-brown urine was obtained by catheter, and analysis showed a pH of 7.5, a + test for albumin and no sugar, the sediment contained numerous fresh red cells, many

epithelial cells and 1 or 2 white cells per high-power field. No bacteria or casts were noted. Examination of the blood disclosed a red-cell count of 4,100,000, with a hemoglobin of 10.5 gm, and a white-cell count of 24,000, with 91 per cent neutrophils. The nonprotein nitrogen was 133 mg per 100 cc. The sodium was 137.3, the potassium 6.3, the carbon dioxide 31.0 and the chloride 95 milliequiv per liter. The blood was examined for sulfadiazine, but no trace was found.

X-ray examination of the chest showed cardiac enlargement, the cardiothoracic ratio being 13.23, but the configuration was not characteristic of a particular lesion. The wall of the aorta showed calcification. No fluid was present in the pleural sinuses, and there were irregular areas of increased density at both bases. The pulmonary markings were everywhere a little prominent, but no gross areas of collapse or consolidation were seen. A plain film of the abdomen showed gas-filled loops of large bowel and of a portion of the small bowel, possibly ileum. Cystoscopy and retrograde pyelograms were negative. No urine, however, was obtained from either pelvis. Instilled fluid returned clear from the right pelvis and slightly blood tinged from the left.

During the next few days there was no improvement. The patient passed no urine, 30 cc of bloody urine being obtained by catheter on the third hospital day. The fluid intake averaged 600 cc a day. The costovertebral-angle tenderness persisted, and nausea, muscular twitching and a positive Chvostek sign developed. The nonprotein nitrogen rose to 154 mg per 100 cc. On the fourth hospital day the patient expired.

DIFFERENTIAL DIAGNOSIS

DR. CHARLES L. SHORT: The first question that we must answer is, What was the nature of the original infection that apparently began three weeks before admission? This was presumably in the respiratory tract and suggests bacterial pneumonia. Perhaps we shall be helped by the x-ray films of the chest. May we see them now?

DR. STANLEY WYMAN: I do not believe that the films will be helpful. They show a large heart and a few small, indefinite linear areas of density in both bases, which, I suppose, lie in the lower lobes. I do not see frank consolidation.

DR. SHORT: Does that picture suggest infection rather than congestion?

DR. WYMAN: It is the picture one sees in atelectasis in any patient lying in bed with some impairment of diaphragmatic motion.

DR. SHORT: Does the film of the abdomen show any definite point of obstruction or rather suggest ileus?

DR. WYMAN: The film of the abdomen is more in keeping with ileus than with true intestinal obstruction.

Examination of the blood showed a hemoglobin of 14.6 gm and a white-cell count of 10,500, with 68 per cent neutrophils. The serum protein was 6.9 gm and the nonprotein nitrogen 28 mg per 100 cc., and the chloride 105 milliequiv per liter. The urine was normal.

An x-ray film disclosed a round, soft-tissue mass between the heart and the dorsal spine measuring

episodes of gastric eructations and had been on a bland diet for eight years. Apparently, he had not lost weight except when he tried to lose it. Two months before entry he had difficulty in swallowing. With this difficulty in swallowing he did not lose much weight, — only 16 pounds, — and on physical examination he was "a well nourished, heavy-set man." We believe that if a person has at least 5

FIGURE 1

about 8 cm in diameter, that caused the barium to deviate toward the right and posteriorly and spread the esophageal lumen into a flattened, semi-circular area (Fig 1). The stomach and duodenum were outlined normally. The heart and lung fields were not remarkable.

On the fourth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR LEFOY SCHALL This patient had a history of the development of midsternal pain during eating fifteen years previously, and a diagnosis of cardiovascular disease was made at that time. Was this pain really sharp pain or merely distress? Did it radiate to the back or to the shoulder? Was it relieved when he regurgitated food? Apparently it was. He had

mm of esophageal lumen he can swallow well masticated food and that so long as he can keep up fluid intake he will not have too much weight loss.

Could the symptoms presented in this case have been due to carcinoma? At the age of forty-three years, they could. Yet pain is not an early symptom of carcinoma. If there is ulceration there may be pain on swallowing. There was no history of an esophagoscopy or biopsy. The x-ray report mentions a flattened esophageal lumen, and I take it that the lumen was also deviated. I do not believe that this was carcinoma of the esophagus because the symptoms were not present long enough. Pain is unusual, — except late in the course, — and there had not been sufficient weight loss.

There was a nodule in the thyroid gland. I do not know whether this is a red herring or not,

PATHOLOGICAL DISCUSSION

DR MALLORY Autopsy showed interesting kidneys. They weighed 450 gm., and for a woman of eighty-nine that is significant hypertrophy. The surfaces were mottled and purplish red, and the capsules stripped fairly readily. When the organs were cut it was found that the entire cortex of both kidneys was infarcted, presenting the gross picture of diffuse cortical necrosis. This is seen most frequently — in about 2 out of every 3 cases, I should say — in young women during the terminal stages of pregnancy or in the first few days following delivery. At the age of eighty-nine that possibility need not be considered. Cortical necrosis has been seen in a scattered variety of other conditions and is occasionally seen in male patients.

When we examined the sections of the kidneys microscopically another possibility was brought up. In all sections there were many small arteries showing the typical changes of periarteritis nodosa. A few arteries outside the renal substance also showed the same lesion — few indeed, but some. There was a characteristic lesion in one adrenal gland, a few changes in the perirenal fat tissue, and a single lesion in the heart. Diffuse involvement of the small renal arteries with periarteritis nodosa might produce the same total infarction of the cortex that one sees in so-called "primary cortical necrosis." I think that the way in which this case should be classified remains debatable. The facts that the arterial lesions were so characteristic of what one sees in periarteritis nodosa and that at least a few lesions were found in organs other than the kidneys lead me to make periarteritis nodosa my primary diagnosis.

The other changes found were only those that one might expect to find in a very old person, — extremely severe arteriosclerosis of the aorta, with multiple ulcerated atheromas and secondary thrombi, — but the main renal arteries were not markedly involved. The heart was hypertrophied, and the lungs were emphysematous, the gall bladder was filled with small stones, and the bile ducts were patent.

DR SHORT What did the tubules show?

DR MALLORY The glomeruli and all tubules in the cortex were completely necrotic, a picture exactly like that of infarction, except that it was symmetrical and diffuse throughout the entire cortex of both organs.

DR FLETCHER H. COLBY Were you able to determine which arteries were responsible?

DR MALLORY In cases of idiopathic cortical necrosis, vascular changes are variable and inconsistent. There are usually necrosis and thrombosis within the actual areas of infarction, but vascular lesions are not found outside. Not all cases show vascular changes, so that it is difficult to attribute the cortical necrosis to a primary mechanical obstruction of the arteries. The pathogenesis of primary cortical necrosis remains a complete mystery.

DR COLBY Presumably toxic?

DR MALLORY A similar lesion has been produced in experimental animals with staphylococcus toxin, but in human beings there is rarely evidence of an infectious etiology. In this case the finger of suspicion points strongly to sulfonamide sensitivity. It is interesting, however, that no trace of persisting sulfonamide, either free or acetylated, could be found in the blood plasma.

CASE 33182

PRESENTATION OF CASE

A forty-three-year-old Jesuit brother entered the hospital because of midsternal pain during eating.

Fifteen years before entry the patient had begun to have midsternal pain that occurred during eating and was relieved when he ceased to eat. An x-ray film was taken at that time, and he was told that he had spasm of the esophagus. Subsequently, he began to have episodes of gaseous eructation and epigastric distress. Seven years later he had been put on a bland diet, which he had continued to follow ever since. Nevertheless, the symptoms continued essentially as before. In addition, he had intermittent bouts of diarrhea with left-sided and lower abdominal cramps. There had been no melena. Two months before entry the patient began to have difficulty in swallowing. When he tried to force food down he developed a severe pain in the right side of the chest. On two occasions he regurgitated undigested food. A month before entry he became unable to belch — such eructation had previously given him some relief. An x-ray film was stated to have revealed "a tumor" in the esophagus. The patient had lost 16 pounds during the year before entry, during which he had been making conscious efforts at weight reduction by means of dietary restrictions. The only other complaint was intermittent pain in the right knee radiating up and down the leg and occurring after protracted standing.

Physical examination revealed a well nourished, heavy-set man. A firm nodule, 0.5 cm. in diameter, was palpable in the left lobe of the thyroid gland, and there was a similar nodule just above the isthmus. Examination of the heart and lungs was negative. There was tenderness in the epigastrium just below the xiphoid but no spasm or palpable masses. The medial aspect of the right knee was slightly tender, but motion was normal.

The temperature, pulse and respirations were normal. The blood pressure was 125 systolic, 75 diastolic.

THE TAFT BILL

THE Taft Bill (S. 545), which was introduced on February 10, 1947, is meeting with considerable approval and support from organized medicine. The Massachusetts Medical Society has endorsed many of the stated objectives of previously proposed national health legislation but has opposed revolutionary trends. It considers universal compulsory insurance undesirable and unnecessary, since the American public, physicians and governmental agencies are not ready for it. It believes that present progress is satisfactory and should be continued, instead of making a reckless leap into the realms of medical bureaucracy. Even if compulsory insurance eventually proves to be necessary, there should be an evolutionary change.

Organized medicine makes no claim that present medical care is adequate. It is still far short of meeting the needs of all the people. But the medical profession is trying to preserve values, and it appears that a good beginning has been made. Voluntary health insurance is rapidly expanding. The Blue Cross now has a membership approaching 30,000,000 in the Nation and about 2,000,000 in Massachusetts. The revised June contracts of the Massachusetts Blue Cross will provide comprehensive coverage of all hospital charges. The Massachusetts Blue Shield is also doing well with a membership greater than 500,000. Rapid expansion is anticipated after the adoption of the revised June schedule, which will give complete surgical and obstetric care outside the hospital, as well as medical and surgical care in the hospital. To the few in the medical profession who have thus far failed to support this voluntary insurance program, it can only be pointed out that the definite trend toward one of two schools of thought — compulsory and voluntary — will eventually necessitate a decision to co-operate.

The Taft Bill aims to preserve and foster existing agencies and to ensure the continued independence of the American people and the medical profession. Briefly, it plans to bring together all the scattered federal health activities into a single national health agency, headed by an outstanding physician. It would provide grants-in-aid to states for the extension of medical care to people unable to pay for it, amounting to \$200,000,000 a year for general surgical and medical services and to \$20,000,000 a year for dental services, the states to match these grants-in-aid on a variable basis. It aims to encourage voluntary prepayment plans and to extend federal grants to pay the subscriptions of indigents, and it allows federal employees, through individual choice, to join voluntary health-insurance plans by payroll deductions. It would determine actual medical needs by requiring state surveys financed with federal subsidies, and it would provide grants-in-aid for research, especially in neuropsychiatry and dental health. It would also require states to have periodic medical and dental examinations of school children, if the parents cannot afford such services.

but could it have been a thoracic thyroid gland? I have not yet seen the x-ray films and do not know whether the obstruction was situated high or low, but the report says that there was a round mass behind the heart that had flattened the esophagus. I doubt whether this could have been a thoracic thyroid gland.

I do not believe that the patient had cardiospasm. In cardiospasm it is the lower end of the esophagus that is involved. He had distress and regurgitation of food, but there was no substernal pain. The x-ray film may show whether or not there was a real cardiospasm with dilatation of the esophagus above.

Could this have been a mediastinal cyst? I do not believe that it was a pulsion diverticulum, which generally involves the upper end of the esophagus and is most unusual in this area. Traction diverticulum is usually due to adhesions, perhaps from the vertebrae, that pull the esophagus out. I rule out traction diverticulum of the esophagus in this area because it is usually higher.

Could this have been a new growth of the mediastinum? Dermoid tumors usually involve the anterior mediastinum. This growth was posterior, between the heart and the esophagus. Could something outside have caused pressure between the heart and the mediastinum?

There was no history of respiratory difficulty, so that, whatever the lesion, it was too low to cause pressure on the large bronchi. This area is too low for aneurysm. The mucosa appears intact, which is strong evidence against carcinoma. I shall therefore consider benign lesions of the mediastinum, among which are tuberculous lymphadenitis and Hodgkin's disease, although nothing in the history suggests tuberculosis. A gumma should also be considered, but I do not believe that it is likely.

The most probable diagnosis is a cyst of the mediastinum.

DR CHESTER M JONES: Would you include neurofibroma as a possible cause of the mass?

DR SCHALL: I do not know. A neurofibroma may be a primary tumor of the mediastinum.

DR JONES: This mass was posterior, and neurofibroma should undoubtedly be included.

DR SCHALL: Yes, let us say that Hodgkin's disease, noninfectious lymphadenitis, tuberculous lymphadenitis and gumma are all possibilities, but I am in favor of a cyst.

DR TRACY B MALLORY: Is there anything further from the x-ray point of view?

DR STANLEY WYMAN: As Dr Schall has said, the mucosa is intact. The barium has been forced into a thin shell over the mass, and the deviation is more apparent to the right. The mass appears to arise outside the mucosa of the esophagus, which is not involved. The question is, Does it arise in the esophageal wall without arising in the mucosa?

DR SCHALL: We must think of the myomatous group of tumors, if the mass arose from the wall. I do not believe that it was a lipoma, because that is pedunculated and is usually at the upper end extending down into the esophagus.

DR W WILSON SCHIER: Could a vascular tumor, such as cavernous hemangioma, have arisen there?

DR RICHARD H SWEET: I have seen only one such case. This was in a patient on whom I operated a few weeks ago. The tumor was in the superior mediastinum.

DR MALLORY: Dr Sweet, will you tell the findings at operation?

DR SWEET: There were two reasons why we made a preliminary diagnosis of intramural benign esophageal tumor in this case — without the benefit of esophagoscopy, I might add. In the first place the x-ray appearance seemed to us, and I believe to Dr Schatzki or whoever interpreted the films, to be characteristic of that type of tumor. The other reason was the nature of the symptoms. The patient really had to work hard to get anything through the esophagus. He had a good deal of discomfort, and a benign tumor or cystic tumor of the mediastinum of such relatively small size in my experience does not give dysphagia of the severity that he had or so much pain or discomfort. For these two reasons we thought that this was an intramural esophageal tumor.

The tumor lay toward the right. We exposed it on the left side of the chest and dissected it from behind the heart and from the right chest. We found that the longitudinal muscle fibers were spread out in such a way that groups of fibers were separated from one another, but by incising the muscularis, we could dissect it free. We broke into it and discovered that it was cystic. The mucosa was not involved. We were able to shell the cyst out of the wall of the esophagus and restored continuity by suturing the muscularis together.

CLINICAL DIAGNOSIS

Benign tumor of esophagus

DR SCHALL'S DIAGNOSIS

Cyst of mediastinum

ANATOMICAL DIAGNOSIS

Congenital tracheobronchial cyst of esophageal wall

PATHOLOGICAL DISCUSSION

DR MALLORY: Microscopically, sections of this cyst showed a considerable amount of inflammation and destruction of the lining epithelium over many areas, but in some spots ciliated columnar epithelium persisted, which established it as a congenital cyst of misplaced tracheobronchial epithelium. The location was not far from the spot where tracheobronchial fistulas are seen in early life.

MICHAEL ALOYSIUS TIGHE

1882-1947

Michael Aloysius Tighe was born at Meriden Connecticut, and moved to Lowell at an early age. He was a graduate of St. Patrick's Boys' School and attended St. Francis Preparatory School in Brooklyn, New York. After graduating from Boston College, where he received an A.B. degree in 1903, he entered Harvard Medical School, receiving his M.D. degree in 1908. He soon established himself in practice in Lowell and was immediately appointed to the surgical staff of St. John's Hospital, where he served for nearly forty years, being chief of the surgical staff at the time of his death. His faithful service to his patients and to the hospital can never be adequately measured.

For a number of years he held the office of city physician and was at one time associate medical examiner for the Northern Middlesex District. He had been president of the Middlesex North District Medical Society.

Early in his medical career Dr. Tighe became a councilor of the Massachusetts Medical Society. His experience on matters of general medical and public concern began about the time the Workmen's Compensation Act was passed in 1912. He believed that the Act should be amended for the general good. He visited various district societies and presented his arguments in a convincing manner and later appeared before the Legislature. The Act was amended and has since proved to be a most satisfactory piece of legislation. Subsequently he was an important figure in questions of public relations and his opinions were eagerly sought by laymen and members of the profession. He had an uncanny sense of seeing through debatable points quickly and was able to clarify muddled discussions in the form of a motion clearly and briefly stated. He was always an important member of a committee, but he never assumed a leading role unless his opinion was fortified with plainly stated facts and sound logic.

Because of his wide knowledge of subjects pertaining to the Society, he was appointed secretary in 1941, a position that he filled capably for nearly six years. Through his faithful, diligent and

efficient work he will undoubtedly be recognized as one of the outstanding secretaries of the Society, and he will always be remembered as the "war secretary." Only a man of high ideals and fine motives could have carried on so successfully through those many troublesome years and have still been held in such great esteem and respect. In addition, he believed that the Society should render more service to its fellows, and for that reason gave much needed aid and sympathetic advice to returning veterans and new members.

It was largely through his rapt devotion to his secretarial duties that he won the real affection and friendship of all members of the Society.

His clear thinking was made evident by the excellent manner in which he expressed himself, his enunciation showing care and forethought. By nature he combined gentleness with sensitiveness. He was appreciative of the finer things in life. He stood for justice and fairness, and he insisted on the truth as he saw it. In heated arguments he kept his dignity and poise and never created animosity. Indeed, he was

a cultured and scholarly gentleman.

He had traveled considerably both in this country and abroad. Besides enjoying prose and poetry, he derived a great deal of pleasure from golf — not only for the game itself but also for the companionship that it afforded. He adored his family, and the evening before his death, all members gathered at his home for the celebration of his birthday.

Dr. Tighe was a fellow of the American College of Surgeons, American Medical Association and New England Obstetrical and Gynecological Society and a member of the Harvard Club of Boston and Longmeadow Golf Club of Lowell.

He is survived by his widow, three sons, a daughter, five grandchildren and two sisters.

Impressive rites for Dr. Tighe were held at the Church of the Immaculate Conception in Lowell. The extremely large attendance by physicians from all parts of the Commonwealth, nurses, hospital executives, friends and former patients attests the high regard in which he was held.

The objective of adequate medical care is to make it available to all the people regardless of financial status. Actually the Taft Bill is designed to reach, in particular, the low-income group. This is a special need. For those who can afford it, direct payment or coverage by a voluntary prepayment plan is the responsibility of the individual. The indigent group is now taken care of, after a fashion, by local welfare agencies or private charity. Subsidy from some tax source will probably be needed to provide unusual diagnostic costs and to meet the expenses of catastrophic illness in this group.

The attainment of adequate medical care for all the people should follow an evolutionary process over a long period, with co-operation of all concerned. The Taft Bill seems to be, at least so far, the best framework on which to build the kind of health legislation that the country needs. It is to be hoped that, after conflicting groups have made the necessary compromises that are a proper mechanism for forging laws in a democracy, the foundation of a broad progressive system of medical care will be evolved. In the meantime, this bill warrants the attention and study of every physician who is interested in his own future, the future of organized medicine and the health of the people of the United States.

MAY DAY — CHILD HEALTH DAY

MAY Day, since a Congressional resolution was passed in 1928, has been traditionally Child Health Day. This year its observance is taking a slightly different form than usual. In a world over-ready for tranquillity but overaccustomed to violence, the current May Day will call attention to the fact that accident, not disease, is now the leading cause of death among children. In the interest of accident prevention in the home, the Children's Bureau set aside the week of April 27 in which to conduct a nationwide educational campaign.

Accidents, according to available statistics, now annually take the lives of nearly twenty thousand boys and girls under twenty years of age, and many more thousands are injured and crippled. Most of these accidents are preventable. In 1944, six thousand children under five years of age died from injuries sustained at home. Of these, two thousand died of burns, and thirteen hundred as a result of mechanical suffocation. Human carelessness, as a killer, is taking the place of pneumonia, enteritis, measles, diphtheria, meningitis, poliomyelitis, whooping cough and scarlet fever combined, many of these diseases, as a result of human intelligence effectively applied, are losing much of their terror.

Nothing can be done about the lives that have been lost from accident except to make their numbers stand as a grim reminder of the carelessness with which we live, and a warning that we must devote ourselves to attaining a better record for the future. Much can be done for the uncounted thousands who have survived their injuries and still live on as more or less permanent cripples.

Many of these patients are treated under the federal-state crippled children's program, administered by the states and financed largely with federal funds, and more would be cared for if those who need the help could be found. This seems to be one of the present problems, — to find the patient, — since the family frequently does not know of the aid that can be obtained without charge and without regard to financial circumstances.

The fact that accidents are now the leading cause of death among children does not mean that the death rate from accidents has actually risen. What it does mean is that science has been able to effect a decline in the death rate from disease. That decline has not been paralleled in accident prevention by the use of ordinary common sense and an acceptance of responsibility for the welfare of those who still require protection and guidance.

is outside. The ureters do not enter the bladder at all, but make their exit above the brim of the pelvis on either side. The glans is all that indicates the existence of the penis, and projects out from the place where nature intended that organ should be located. An opinion has been given that the bones are not united in the usual manner in front, but are tied imperfectly together by the intervention of a ligamentous band. It strikes us that an effort should be made to lessen this poor wandering boy's sad calamity. If some benevolent gentleman would give him the use of a free bed awhile at the Massachusetts General Hospital,* our unbounded confidence in the ingenuity and skill of the surgeons of that institution, leads us to believe that he might there find at least some relief. — Tuesday, 3rd inst., being the concluding day of the courses, Dr. Warren gave his last lecture to the Medical School. He took leave of his audience, by wishing for his students a continued zeal in the prosecution of their studies, for the candidates for graduation a triumphant passage through the narrow gate that leads to professional honors, and for the young practitioners abundant opportunities of relieving the poor and, adequate reward of their labors from the rich, and, above all, a conscientious discharge of their duties through life. — At the meeting after the close of the exercises, Dr. C. T. Jackson was called upon by Dr. Bigelow to speak in regard to the insensibility to pain produced by inhalation of sulphuric ether vapor. Dr. Jackson would only re-assert that he discovered that insensibility to pain was produced by such inhalations and that he communicated the fact to one of his pupils in February, 1846, and requested him to try the experiment when he had a tooth extracted. He regretted that any misunderstanding should have arisen concerning the discovery. He was willing to allow great credit to others for their enterprise and zeal in promoting its introduction, and for skill in improving his originally simple apparatus. Yet it would certainly be unwarrantable for the miner, who carried Davy's safety lamp into the fire damps of a mine, to dispute the claims of its original inventor, for he received that instrument already proved to be efficient, with the assurance that it would guide him in safety amid the explosive gases of the mine. — Extracted from the *Boston Medical and Surgical Journal*, March, 1847.

R F

*The records of the Massachusetts General Hospital reveal that in January, 1846, J. H., nineteen years old, was admitted to the Surgical Service for congenital malformation of the urinary organs and was discharged unrelieved.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

SMALLPOX PROGRAM FOR MASSACHUSETTS

The appearance of 8 cases of smallpox in New York City recently, with a total of 2 deaths, has

given rise to considerable and unwarranted concern. The fear that this disease may attain even larger epidemic proportions has been recently aggravated by the misinterpretation of a radio report of a small-pox outbreak within an institution.

There has been no reported case of smallpox within Massachusetts for the past fifteen years. In the event of the occurrence of this disease within Massachusetts, a program has been formulated for the care and treatment of such cases. If the diagnosis of smallpox is suspected in any one case, it is imperative that the state or local health department be notified immediately.

The Biologic Laboratory of the Massachusetts Department of Public Health has on hand sufficient vaccine to satisfy requests at a normal demand level. Personnel from other divisions of the Department of Public Health is being diverted to assist in the present work of increasing the present supply of smallpox vaccine. Physicians are cautioned, however, that in the event of a panic concerning the New York epidemic, the demand for vaccine will far exceed the supply.

To clarify the status of smallpox in Massachusetts, a conference of public-health officials representing the Massachusetts Department of Public Health and the Boston Health Department was called, and the following recommendations were adopted:

- No mass vaccination of the general public is indicated.
- Priority for use of the present supply of vaccine shall be restricted in the following order:
 - (a) To actual contacts of cases.
 - (b) To physicians, nurses and hospital personnel.
 - (c) To unvaccinated persons traveling to areas of small-pox prevalence.
 - (d) To infants six to twelve months of age and for re-vaccination of preschool children prior to entering school.

The above information has been forwarded to all hospitals, medical societies and boards of health within the Commonwealth.

DIAGNOSTIC TESTS FOR CERTAIN VIRUS DISEASES

For the present the Department has available, through a co-operative arrangement with Harvard Medical School, facilities for making a limited number of serologic tests for Influenza A and B by the red-cell agglutination inhibition technic, for mumps, psittacosis and lymphogranuloma venereum by complement-fixation tests and for lymphocytic choriomeningitis by neutralization tests.

Specimens should be submitted in the Department's special outfit and accompanied by properly filled out forms entitled "Request for Serological Tests for Certain Virus Diseases." The special outfit to be used, which is the same as the Department's undulant-fever outfit, and the special forms to be filled out may be obtained from local boards

MASSACHUSETTS MEDICAL SOCIETY

BUREAU OF CLINICAL INFORMATION

All secretaries of various medical groups such as special societies and alumni associations, are requested to notify the Bureau of Clinical Information regarding scheduled meetings, annual dinners and so forth. If such data are on file, it is hoped that duplication of dates can be avoided.

ANNUAL GOLF TOURNAMENT

The annual golf tournament of the Massachusetts Medical Society will be held at the Woodland Golf Club, 1897 Washington Street, Newton, commencing at 1 00 p m on Tuesday, May 20. Prizes for low gross and net scores will be awarded, as well as the Burrage Bowl, emblematic of the championship of the Society.

Dr Henry W Godfrey has been appointed chairman of the Golf Committee, and entries should be sent to him at 14 Hancock Street, Newton. Post entries are allowed.

There will be an opportunity to have dinner at the club for those who desire it.

SIDNEY C WIGGIN, *Chairman*
Committee on Arrangements

DEATHS

PERKINS — George E Perkins, M D, of Belmont, died April 3. He was in his seventieth year.

Dr Perkins received his degree from Georgia College of Eclectic Medicine and Surgery in 1913. He was a fellow of the American Medical Association. He was a member of the staffs of the Boston Dispensary and the Massachusetts Memorial Hospitals and was acting director of the Division of Venereal Diseases, Massachusetts Department of Public Health.

His widow survives.

STONE — Henry E Stone, M D, of Boston, died March 31. He was in his fifty-sixth year.

Dr Stone received his degree from Tufts College Medical School in 1912.

His widow and a son, Dr Nathaniel M Stone, survive.

A HUNDRED YEARS AGO

As they threatened, the Physicians of Berkshire County have petitioned the Great and General Court of Massachusetts for new legislation concerning the Massachusetts Medical Society. At present, they claim, its meetings, its funds and its library are confined in Boston, at the eastern extremity of the Commonwealth so that the portion of the profession residing in the *opposite extremity* can derive little or no benefit from either. They ask that the State Medical Society may be so re-organized that a participation of the funds and library already accumulated may be secured to County Medical Societies or that the County of Berkshire may be constituted a separate and distinct medical society, clothed with

the usual powers and privileges pertaining to such bodies — The Counsellors of the Massachusetts Medical Society deprecate this action. It can be shown, they say, that more property has been given by the parent Society to the County of Berkshire than the whole amount of assessments ever received by the Society from them. The library of the Society is a small collection of old books, the result entirely of donations and legacies. It is but little used in Boston, and by a regulation of the Society, any District Society may carry off sixty volumes at a time for the use of its members. Of this privilege the County of Berkshire has freely availed itself. If by "the usual powers and privileges" of medical corporations, it is intended to include the power of conferring *licenses to practice physic*, this power becomes dangerous and liable to abuse. If such a power is granted to the physicians of Berkshire, there is no reason why the physicians of any other county in the Commonwealth may not claim the like privilege. And thus the State might be cut up into small and irresponsible tribunals, disposing of licenses for a pecuniary compensation, and not accounting to any higher authority for abuse — which might result from the misuse of their privileges — An exhibition of extraordinary interest to humanity occurred at the Massachusetts General Hospital on Saturday last. A patient was presented who, we understand, was laboring under paraplegia, having its origin in a caries of the lower dorsal vertebra, and for which Dr Warren proposed the actual cautery. After the patient had inhaled the letheon, Dr Warren run an iron rod, heated to a white heat, to the length of about two feet, up and down the back, each side of the spine, burning two lines on one side and one on the other, and then carried it zigzag across, between the spinous processes, the same distance. The patient during this process was wholly unconscious of pain, under the severest test to which he could be subjected — that of a hot iron applied to the naked skin — Dr Ames of Wayland, Mass., in forty-one operations drew from a lady in that town, who died not long since, *fourteen hundred pounds of water!* On one or two occasions two pailsful of fluid were taken away at the same time. The lady, immediately after each operation, till towards the close of life, was so completely relieved that she at once assumed the management of her domestic duties. There may have been more remarkable cases on medical record, but nothing, we believe, more striking has occurred in this region — A young native of Chester, Vt., J H, 19 years old, who is maintained chiefly by the benevolent contributions of medical gentlemen, on whom he calls while travelling over the country, exhibits in his person, one of the most extraordinary and inconvenient malformations imaginable. In the first place there is only a portion of a bladder, about the size of a hen's egg, and that inverted — and instead of being within the cavity of the abdomen, it

Women in Industry. Their health and efficiency. By Anna M. Baetjer, Sc.D. Issued under the auspices of the Division of Medical Sciences and the Division of Engineering and Industrial Research, National Research Council. Prepared in the Army Industrial Hygiene Laboratory. 8°, cloth, 344 pp., with 122 tables. Philadelphia and London W B Saunders Company, 1946.

This study was made during World War II for the purpose of ascertaining the utilization of womanpower in industry to further the war effort. An exhaustive critical review was made of the literature to determine whether such utilization had a sound physiologic basis. The material is well documented with graphs and statistical tables. The text is divided into main sections, comprising seventeen chapters, and four appendixes, as well as a bibliography of twenty-two pages. The sections deal with the following aspects of the subject: the physique of women in relation to work, fatigue and physical stress, absenteeism due to sickness, accidental injuries, occupational diseases, gynecologic and obstetric problems and mortality and fertility in relation to occupation.

This monograph presents information about the ability of women to perform operations previously considered suitable for men only and also gives a clear picture of the facts known about the relation of employment to the health of women. It is not the intention to justify the employment of women in industry but to make available valuable information for the proper job placement of women when their service is required. The study endeavors to present the scientific facts known concerning the health and efficiency of women in relation to their employment on the basis of the literature and the information gained during the war, and to indicate phases of the problem requiring further investigation, to obtain maximum health and working efficiency. Section seven is devoted to a summary and lengthy conclusions in which each main section is treated separately and all pertinent facts relative to each are analyzed. The appendixes comprise valuable collateral information, including a table showing the distribution of gainfully employed women according to occupational classes and industrial groups as shown by the 1940 United States Census, a list of occupations suitable for women and a summary of state labor laws for women as of 1944. In addition to the main bibliography, selected references are appended to each chapter.

The material is well organized, and the text well printed on good paper. This monograph should be in all medical libraries and should prove valuable to all industrial physicians.

Water Treatment and Purification. By William J. Ryan, M.E. Second edition. 8°, cloth, 270 pp., with 66 illustrations. New York and London McGraw-Hill Book Company Incorporated, 1946. \$2.75.

This manual, first published in 1937, has been revised to include descriptions of processes that have come into use since the issue of the first edition. These include organic ion exchange, materials for water softening, acid absorbents, demineralization, the treatment of boiler water to prevent embrittlement, new equipment for accelerating the lime-and-soda ash softening process, new developments in the use of chlorine for sterilization and the stabilization of water to prevent scale deposits.

Although this manual has been written primarily for engineers and others concerned with water purification, it should prove useful to all persons interested in pure water and water supply. The chapters on impurities, sedimentation and coagulation, filtration and water analysis are of public-health interest. The material is well organized, well written and printed with a good readable type on good paper. The manual is recommended for reference purposes.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Three Unpublished Drawings of the Anatomy of the Human Ear. By the late Max Brödel with the assistance of P. D. Malone, Stacy R. Guild and S. J. Crowe. 4°, cloth 9 pp.

with 4 illustrations and frontispiece. Philadelphia W B Saunders Company, 1946. No charge.

Max Brödel, 1870-1941, pioneer medical artist, long connected with the Johns Hopkins University School of Medicine, is honored in this publication by the W B Saunders Company. These unpublished drawings are excellent examples of the high quality of work executed by Brödel, and are thoroughly characteristic of his style. They are presented to the medical profession as a tribute to the memory of a great artist in his chosen field.

The Normal Electroencephalogram. By Leo M. Davidoff, M.D., professor of clinical neurological surgery, Columbia University College of Physicians and Surgeons, and attending neurologic surgeon, Montefiore Hospital, New York City, and Cornelius G. Dyke, M.D. Second edition, thoroughly revised. 8°, cloth, 252 pp., with 155 illustrations. Philadelphia Lea and Febiger, 1946. \$5.50.

This second edition of a standard monograph has been revised on the basis of an accumulation of over eight thousand electroencephalograms, more than double the number available for the first edition. The text is well printed with a good type, and the illustrations are excellent. The book is recommended to all medical libraries and to neurologists and physicians interested in the subject.

Exercises in Electrocardiographic Interpretation. By Louis N. Katz, M.D., director of cardiovascular research, Michael Reese Hospital, Chicago, and professorial lecturer in physiology, University of Chicago School of Medicine. Second edition, thoroughly revised. 4°, cloth, 288 pp., with 141 illustrations. Philadelphia Lea and Febiger, 1946. \$6.00.

This manual, a companion volume to the author's large work on the same subject, has been revised to conform to the advances in electrocardiography. The total number of cases has been increased to one hundred, and thirty-eight have been discarded and new ones substituted. The descriptions and interpretations of the other cases have been revised to conform to the newer terminology of the subject. The work is written for persons requiring practice in reading unknown electrocardiograms. The book is well published in every way and should prove valuable to students of the subject.

Clinical Electrocardiography. By David Scherf, M.D., associate professor of medicine, New York Medical College, Flower and Fifth Avenue Hospitals, and Linn J. Boyd, M.D., professor of medicine, New York Medical College, Flower and Fifth Avenue Hospitals. Second edition. 4°, cloth, 267 pp., with 243 illustrations. Philadelphia J B Lippincott Company, 1946. \$8.00.

This second edition of a standard work has been thoroughly revised by the addition of new material. Some sections have been completely revised, whereas others have been expanded. Extensive bibliographies are appended to each part. The text is well printed in a two-column format.

Urologic Roentgenology. By Miley B. Wesson, M.D. Second edition, thoroughly revised. 8°, cloth, 259 pp., with 258 illustrations. Philadelphia Lea and Febiger, 1946. \$5.50.

In this new edition of a standard work, the text has been practically rewritten, and the literature brought up to date. Many of the illustrations have been deleted, and new ones substituted. The purpose of the book is to provide a manual for beginners in the field of urography. The first chapter furnishes a short history of the subject. The material is well organized, and the text is well printed with a good readable type. The book should prove useful to physicians interested in the subject.

A Primer for Diabetic Patients. An outline of treatment for diabetes with diet, insulin and protamine-zinc insulin, including directions and charts for the use of physicians in planning diet prescriptions. By Russell M. Wilder, M.D., Ph.D., professor and chief, Department of Medicine, Mayo Foundation, University of Minnesota, and senior consultant, Division of Medicine, Mayo Clinic. Eighth edition, reset. 18° cloth, 192 pp., with 8 illustrations. Philadelphia and London W B Saunders Company, 1946. \$1.75.

This standard manual for diabetic patients, first published in 1921, has been slightly revised to conform to minor

of health or directly from the State Diagnostic Laboratory, 281 South Street, Jamaica Plain 30

In each suspected case, two aseptically collected 4-cc serum specimens are required, the first taken as soon as possible after the onset of the disease, and the second ten to fourteen days later (four to five weeks later in cases of lymphocytic choriomeningitis). If facilities for separation of serum are not available, 10 cc of clotted blood for each specimen may be substituted if it is mailed to the laboratory at once. *Since positive diagnosis can be made only if a rise in antibody titer is demonstrated during the course of the illness, two specimens must be sent.* Tests for diagnosis, therefore, will be run only on paired specimens. If information regarding past mumps infection and consequent immunity alone is desired, however, only one specimen need be submitted.

For information regarding serologic diagnosis of other virus infections, the State Diagnostic Laboratory, 281 South Street, Jamaica Plain 30 (telephone, ARNold 5440), should be consulted directly.

It should be noted that none of these tests will assist in the confirmation of a diagnosis during the early acute stage. They are useful mainly in making a diagnosis in retrospect.

If intelligent selection is exercised by physicians in sending in specimens, this service may be made permanent by the Department. Because funds are limited for reimbursing Harvard Medical School for the tests, the service will have to be discontinued if lack of selection results in too large a volume of tests.

NEW APPOINTMENTS

Mary E. Spencer, Ph.D., nationally known health educator and author of several books, has been appointed chief of the Bureau of Health Information of the Massachusetts Department of Public Health. Dr. Spencer is well known in Washington circles for her work as director of the Health Education Bureau of the National Welfare Conference, in which position she represented the United States at the World Federation of Education Association at Geneva. She also served on the Hoover White House Conference on Child Health and Protection. Prior to her appointment, Dr. Spencer held the position of director of health education in the schools of Malden. She is professor of public health at Wellesley College Graduate School of Hygiene. She is vice president of the Massachusetts Public Health Association, chairman of health and nutrition of the American Association for Health, Physical Education and Recreation and a former president of the New England Health Education Association. She is the author of the textbooks *Health Education for Teachers* and *Health Through the School Day*, as well as numerous professional articles.

Eugene R. Sullivan, M.D., has been appointed assistant director in the Division of Biologic Labora-

tories, Massachusetts Department of Public Health. Dr. Sullivan, recently a lieutenant colonel in the Army Medical Corps, served three years overseas as chief of laboratories, Sixth General Hospital, consultant on blood and blood transfusions for the North African and Mediterranean theaters of operations and a member of a board for the study of the treatment of the seriously wounded. Prior to his Army service, Dr. Sullivan held positions at Harvard Medical School, Massachusetts General Hospital and Michigan University School of Public Health, working in the fields of internal medicine, infectious disease and laboratory sciences.

Martha Howard Fales, B.A., formerly dental health consultant, Michigan Department of Health, has joined the staff of the Massachusetts Department of Public Health, Division of Dental Health, as public-health dental-hygiene supervisor.

Julian M. Karasoff, D.V.M., has been appointed veterinary food inspector in the Division of Food and Drugs, Massachusetts Department of Public Health. Prior to his appointment, Dr. Karasoff practiced privately as a veterinarian. He also served as slaughtering inspector in Waltham.

Salvatore R. Traina, M.D., formerly command surgeon, Seventh Air Service Area Command in Tokyo, is now serving as physician in charge of the mobile unit of the State Blood Donor Program, Division of Biologic Laboratories, Massachusetts Department of Public Health. Prior to his appointment, Dr. Traina served for twenty-eight months in the Asiatic-Pacific Theater, being discharged with the rank of major in the Medical Corps. He is a diplomate of the National Board of Medical Examiners.

Barbara Ford Carter, M.D., has been appointed assistant district health officer of the North Metropolitan District, Massachusetts Department of Public Health. Dr. Carter was formerly house officer and assistant resident, Third Medical Service, Boston City Hospital.

BOOK REVIEWS

Fees and Fee Bills. Some economic aspects of medical practice in nineteenth century America. By George Rosen, M.D., Ph.D. 4°, paper, 91 pp. Baltimore: Johns Hopkins Press, 1946. \$1.50.

Dr. Rosen in this monograph has made a valuable contribution to the medical economic history of the United States. He has published a number of fee tables from various sections of the country and has shown the gradual changes of professional fees from 1815 to 1891. The fee bill of the Boston Medical Association of 1864 is reproduced from the *Boston Medical and Surgical Journal* of the same year.

It is not generally known that the Boston Medical Association was established for the sole purpose of regulating the fees of physicians and the ethics of the profession. It was formed in 1806 and became extinct in 1910. It published from time to time, beginning in 1808, fee tables and a pamphlet called *Medical Police*, in which ethics and fees were discussed. Its records are now in the Boston Medical Library.

This monograph loses some of its value because of the lack of an index. At least a list of the fee tables should have been published. It should find a place in all medical-history collections, however, as well as in business libraries.

BENIGN AND MALIGNANT TUMORS OF THE SMALL INTESTINE*

THOMAS W. BOTSFORD, M.D.,[†] AND ROY E. SEIBEL, M.D.[‡]

BOSTON

THE small intestine comprises the longest portion of the alimentary canal and yet receives small consideration in the diagnosis of intestinal tumors. The reason is the rarity of neoplasms in the small bowel. Such easy setting aside is in line with the attitude toward these tumors in general and can no longer be tolerated by the profession. Moreover, tumors of the small intestine are possibly curable in the early stages, and certainly the small bowel is heir to a variety of benign tumors that may cause symptoms. The diagnosis of the lesions is usually obscure, and until the physician entertains the possibility, it will remain obscure.

It is the purpose of this communication to stress factors that may aid in the early diagnosis of small-bowel tumors and to review the primary cases seen at the Peter Bent Brigham Hospital. X-ray diagnosis of these tumors is especially emphasized. The material for this report was obtained from the clinical and autopsy records of the hospital from 1913 to 1946. Only histologically verified benign and malignant primary tumors of the duodenum, jejunum and ileum are included. Carcinomas of the head of the pancreas and of the ampulla of Vater are not considered. Several cases in the present series have previously been reported. Oughterson and Cheever¹ and Botsford and Newton² each reported a case of submucous lipoma of the ileum, and Newton and Buckley³ reported one of carcinoma of the jejunum. In 1934 Baile⁴ included 8 instances of argentaffinoma of the jejunum and ileum in his exhaustive study.

A total of 65 cases of primary small-bowel tumor were found, and in 33 of these the tumors were malignant. Shallow, Eger and Carty⁵ state that primary cancer of the small intestine occurs in 0.1 per cent of all cases in which autopsies are performed and is thirty-six times less frequent than malignant tumors of the colon, but that 60 per cent of intestinal sarcomas are located in

the small bowel. Horslev,⁶ however, was able to collect 243 cases of carcinoma of the jejunum and ileum from the literature between 1932 and 1941, it is of interest that in 7 cases the lesions were primary in a Meckel's diverticulum. Benign tumors of the small bowel are also rare, but are probably more frequent than is realized, since they seldom cause symptoms.

TYPES OF TUMOR

The types and location of the tumors are presented in Table 1. Adenocarcinoma was the most frequent tumor, occurring about equally throughout the small intestine, although the percentage localization based on length of bowel indicated a greater incidence in the upper part of the small intestine. Argentaffinoma constituted the next most frequent group, but these tumors were invasive in only 2 cases. Lymphosarcoma, next to adenocarcinoma, was the largest malignant group of clinical significance. The benign tumors—submucous lipoma, adenoma, leiomyoma and fibroma—comprised about a fourth of the whole series and were the cause of symptoms in only 3 cases. Rankin and Newell⁷ reported a higher incidence of symptoms due to benign lesions but did not include argentaffinomas in their series. In 32 cases in our series, in all of which the tumors were benign except for 1 case with a locally invasive argentaffin tumor and 2 with small carcinomas of the duodenum, the lesions were incidental findings at autopsy. A careful review of the corresponding clinical records showed no evidence of their having caused symptoms. Raiford⁸ reported 60 per cent benign lesions and 40 per cent malignant tumors in his series and pointed out that 49 per cent were incidental findings. In our series, the ileum, where lymphosarcomas and argentaffinomas characteristically occur, was the most frequent portion of the small intestine involved. There were 38 men and 27 women. The maximum incidence was in the sixth and seventh decades, but in 10 cases the malignant tumors occurred in pa-

changes in procedure developed since 1941, the date of the seventh edition. The text is written in a practical, non-theoretical manner and is based on the instruction given in the Diabetic School at the Mayo Clinic and on thousands of cases. The material is well organized and well written in plain language. The topics covered include urine testing, administration of insulin, complications, including gangrene, diet and foods.

Wm Beaumont's Formative Years. Two early notebooks, 1811-1821. With annotations and an introductory essay by Genevieve Miller, M.A., Institute of the History of Medicine, Johns Hopkins University. 8°, cloth, 87 pp., with 21 illustrations. New York: Henry Schuman, 1946. \$6.00.

Miss Miller has written an interesting introduction and has provided copious explanatory notes to this reproduction of the two notebooks of Beaumont—one medical and the other general—owned by the Washington University School of Medicine, St. Louis. The first notebook contains excerpts from medical authors, case histories, prescriptions and notes on military medicine. The second contains literary excerpts, including poetry, and war and travel diaries. The book is a credit to the publisher. It is beautiful in conception and should be in all medical libraries and medical-history collections.

New Aspects of John and William Hunter. I. Everard Home and the Destruction of the John Hunter Manuscripts. II. William Hunter and His Contemporaries. By Jane M. Oppenheimer, Bryn Mawr College. With a foreword by Fenwick Beekman, M.D. 8°, cloth, 188 pp. New York: Henry Schuman, 1946. \$6.00.

In these studies Miss Oppenheimer has made a valuable contribution to medical history. In Part I she made a new investigation and a reinterpretation of the destruction of John Hunter's manuscripts by his brother-in-law, Sir Everard Home, based on an analysis of the personal relations existing between Home, Hunter and William Clift. Part II is devoted to an evaluation of the personality of William Hunter, the great obstetrician, as revealed by his friendships with outstanding personages of his time. Likewise, the author discusses his disputes with his famous brother John. Copious notes and bibliographies are appended to both parts. The book is recommended for all medical-history collections.

Paragon Supplement. By Mead Johnson and Company. 8°, paper, 33 pp. Evansville, Indiana: Mead Johnson and Company, 1946. Sent on request.

This pamphlet is a bibliography of art techniques in various mediums especially selected for the physician artist. In addition there are a number of short papers written for the beginner by the officers of the American Physicians' Art Association. The material should prove valuable to all physicians interested in the various aspects of art.

NOTICES

REUNION AT SPRINGFIELD HOSPITAL

A combined reunion of former interns and graduates of the nursing school will be held at the Springfield Hospital on Saturday, May 17. The program will consist of operations and clinics by the medical staff and demonstrations and talks in the classrooms of the Nurses' Residence by the nursing department in the morning. At noon the unveiling of the World War II Memorial will take place in the main lobby of the hospital, following which luncheon will be served in the cafeteria to all the hospital group. The afternoon will be free for visiting and a tea in the living room of the Nurses' Residence, and the reunion dinner will be held at the Hotel Kimball at 7:00 p.m.

MASSACHUSETTS SOCIETY OF EXAMINING PHYSICIANS

The fortieth anniversary meeting and dinner of the Massachusetts Society of Examining Physicians will be held on Wednesday, May 7, at 6:30 p.m., in the State Suite of the Copley-Plaza Hotel, Boston. Dr. James C. White, chief of the Neurosurgical Service, Massachusetts General Hospital, will be the guest speaker and present a paper, illustrated by lantern slides, on the topic "The Contributions of Neuro-

surgery to Problems of Vascular Disease and Visceral Pain." Members of the Society will participate in the discussion, which will be opened by Dr. Charles A. Robinson. Reservations for the dinner may be made with the assistant secretary, Miss Anne Rodman, 157 Fourth Street, Medford, Massachusetts.

JOSEPH H. PRATT DIAGNOSTIC HOSPITAL

30 Bennet Street, Boston

Lecture Hall, 9-10 a.m.

MEDICAL CONFERENCE PROGRAM

Wednesday, May 7—Heparin Therapy of Thromboembolic Disease. Dr. Arnold Starr.

Friday, May 9—Methemoglobinemia and Sulfhemoglobinemia. Dr. C. A. Finch.

Wednesday, May 14—Pediatric Clinicopathological Conference. Drs. James M. Baty and H. E. MacMahon.

Friday, May 16—The Control of Acidic-Fluid Formation in Hepatic Cirrhosis by Albumin, Mechanisms of Albumin Action in Water and Sodium Balance of Other Diseases. Dr. S. Howard Armsirong.

Wednesday, May 21—Porphyria. Dr. Marvin Bloom.

Friday, May 23—The Systemic Manifestations of Rheumatoid Arthritis. Dr. Walter Bauer.

Wednesday, May 28—Clinicopathological Conference. Drs. Richard Chute and H. E. MacMahon.

Friday, May 30—Holiday.

On Tuesday and Thursday mornings, Dr. S. J. Thannhauser will give medical clinics on hospital cases. On Saturday mornings, clinics will be given by Dr. William Dameshek. Medical rounds are conducted each weekday by members of the staff from 12:00 to 1:00 in the Lecture Hall.

All exercises are open to the medical profession.

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING

THURSDAY, MAY 8

FRIDAY, MAY 9

*9:00-10:00 a.m. Methemoglobinemia and Sulfhemoglobinemia. Dr. C. A. Finch. Joseph H. Pratt Diagnostic Hospital.

*10:00 a.m.-12:00 p.m. Medical Staff Rounds. Peter Bent Brigham Hospital.

12:00 p.m.-1:00 p.m. Clinicopathological Conference (Boston Floating Hospital). Joseph H. Pratt Diagnostic Hospital.

MONDAY, MAY 12

*12:15-1:15 p.m. Clinicopathological Conference. Peter Bent Brigham Hospital.

TUESDAY, MAY 13

12:00 p.m.-1:00 p.m. Dermatological Service, Grand Rounds. Amphitheater. Dowling Building. Boston City Hospital.

*12:15-1:15 p.m. Clinicoradiological Conference. Peter Bent Brigham Hospital.

WEDNESDAY, MAY 14

*9:00-10:00 a.m. Pediatric Clinicopathological Conference. Drs. James M. Baty and H. E. MacMahon. Joseph H. Pratt Diagnostic Hospital.

*11:00 a.m.-12:00 p.m. Medical Clinic. Amphitheater. Children's Hospital.

*12:00 p.m. Clinicopathological Conference (Children's Hospital). Amphitheater. Peter Bent Brigham Hospital.

*2:00-3:00 p.m. Combined Clinic by the Medical Surgical and Orthopedic Services. Amphitheater, Children's Hospital.

*Open to the medical profession.

or initiate intussusception. None of the tumors in the 5 cases in this series were the cause of any difficulty. One carcinoma of the duodenum arose in an adenoma.

Fibroma

Two cases of small pedunculated fibroma of the small bowel were encountered as incidental findings. They may cause the same difficulties as leiomyomas.

FIGURE 1 *Adenocarcinoma of the Jejunum*

The photograph of the gross specimen shows a typical annular tumor. Note the dilated proximal portion of the intestine. This tumor was not palpable preoperatively. With the lumen of the bowel opened, the small size of the tumor is more apparent.

Leiomyoma

There were only two leiomyomas, both of which were incidentally found as sessile tumors measuring a few millimeters in diameter. The lesions rarely cause intussusception or undergo sarcomatous degeneration.

SYMPTOMATOLOGY

All observers are agreed that no characteristic clinical picture is associated with benign or malignant tumors of the small intestine. The symptoms due to these lesions, however, are those either of obstruction or of bleeding into the alimentary canal with the development of secondary anemia. The

tients between thirty-five and forty-five years of age. It follows that the majority of small-bowel tumors that cause symptoms are malignant and that about a third of these are seen in patients under fifty years of age.

Carcinoma

Adenocarcinoma is the usual type encountered,⁹ and in our series all the lesions in this group were adenocarcinomas. One tumor of the duodenum arose in an ulcer, and another in the same location

Argentaffinoma

Argentaffin tumors, or carcinoids, arise from the Kultschitzky cells in the depths of the mucosal glands. They are characteristically located in the vermiform appendix and less frequently in the terminal ileum, but are occasionally seen in the stomach, jejunum and cecum. They are usually regarded as benign tumors, but occasionally they become malignant, with local invasion and distant metastases. They grow slowly in contradistinction

TABLE 1 Types of Tumor in 65 Cases

Lesion	Location			Cause of Symptoms	Incidental Finding
	Duodenum	Jejunum	Ileum		
Adenocarcinoma	6	7	5	16	2
Argentaffinoma	0	1	15	1	15
Lymphosarcoma	0	1	12	13	0
Submucous lipoma	1	1	7	3	-6
Adenoma	3	2	0	0	5
Leiomyoma	0	1	1	0	2
Fibroma	0	1	1	0	2
Totals	10	14	41	33	32

arose in an adenomatous polyp. Metastasis to the regional lymph nodes, which occurs early, was grossly present in all but 2 cases at the time of operation or autopsy. It is of special interest that duodenal adenocarcinomas were incidental findings in 2 patients with carcinoma elsewhere in the gastrointestinal tract. The stomach was involved in one patient, and the sigmoid in the other, those lesions being the cause of the symptomatology and the reasons for hospitalization. The typical adenocarcinoma of the small bowel gives an annular constriction to the intestine and is not a large tumor (Fig 1). Distant metastases are frequent late in the course of the disease.

Lymphosarcoma

Lymphosarcoma, which originates in the lymphoid tissue of the bowel wall, generally occurs in the ileum, and the mesenteric lymph nodes are involved early. The lesion is usually diffusely infiltrating and not confined to a small area of the intestine (Fig 2). Because of this, a mass is frequently palpated, in 11 of our patients with lymphosarcoma there was a palpable mass, whereas in only 2 patients with adenocarcinoma was such a mass present. It is of more than academic interest to repeat that most of these tumors were seen in the fourth decade of life.

In this study, lymphosarcoma of origin in the bowel wall was carefully separated from lymphosarcoma or lymphoma originating in the mesenteric lymph nodes. The latter rarely invades the bowel wall, although intestinal symptoms may arise from mechanical causes.

to lymphosarcoma and carcinoma, and radical resection is indicated even in the presence of distant metastases. Four patients had from two to nine multiple tumors. The usual carcinoid is seen at autopsy as a small nodule with a distinctive yellowish color.

There were two malignant carcinoids in our series, both of which have been described by Bailey.⁴ One was found to be invading the mesentery of a patient who had died of an unrelated cerebral tumor. The other, which was the cause of intestinal obstruction, had encircled only part of the circumference of the ileum but had spread to the adjacent mesentery and to the liver. Radical resection of the local lesion was performed. The patient died six years after recognition, and autopsy showed a small local recurrence and extensive liver involvement.

Lipoma

Lipomas of the small intestine are benign fatty tumors located in the submucosa and are usually pedunculated (Fig 3). Their importance clinically lies in the fact that they may initiate an intussusception. This occurred in 3 of our 9 cases. Two of these patients, who were successfully treated and are living and well, have been reported.^{1,2} The third patient had multiple submucous lipomas with intussusception, but the disease was not recognized ante mortem, although it was the cause of death.

Adenoma

Adenomas of the small bowel are small pedunculated tumors that may undergo malignant changes

ous stomach." Although it is obvious that the clinical picture may be obscure, patients with symptoms of chronic intermittent intestinal obstruction or of secondary anemia of gastrointestinal

X-RAY DIAGNOSIS

The accurate early diagnosis of tumors of the small intestine ultimately depends on careful roentgenologic barium-contrast studies. It is our

TABLE 2 *Symptoms in 30 Cases of Malignant Small-Bowel Tumor*

LESION	LOCATION	VOMITING	CONSTIPATION	ABDOMINAL PAIN	GROSS MELENA	SECONDARY ANEMIA	PALPABLE ABDOMINAL MASS
Adenocarcinoma (16 cases)	Duodenum	4	4	1	—	—	—
	Jejunum	5	5	—	—	2	1
	Ileum	4	4	—	—	1	1
Lymphosarcoma (13 cases)	Jejunum	1	1	1	—	—	1
	Ileum	6	6	10	5	—	10
Angiosarcoma (1 case)	Ileum	1	1	1	—	—	1

opinion must have roentgenologic investigation of the small intestine if an adequate explanation is not found in the stomach or colon.

Lymphosarcoma, in our experience, presented a more clear-cut picture, in that an abdominal mass

opinion that any patient with signs or symptoms referable to alimentary-tract obstruction or bleeding should have x-ray investigation of the small intestine, provided a satisfactory explanation for the clinical picture is not found in the esophagus,

FIGURE 3 *Submucous Lipoma of the Ileum*

The tumor was the leading point of an ileocolic intussusception. The diagnosis was made by barium enema.

was palpable in all except 2 patients. Abdominal pain of a crampy nature was also much more frequent, and there was usually no question that these patients had a serious abdominal disease. One patient had an ileocolic intussusception. In addition to the symptoms listed, all the patients with malignant tumors showed evidence of weight loss.

stomach or large intestine. In this respect it is well to remember that a peptic ulcer may coexist with a jejunal or ileal tumor.

Methods of Examination

Unless there is definite evidence of small-bowel obstruction, the course of the x-ray investigation

benign tumors can be the source of considerable blood loss,⁷ although there was no bleeding in our series. Intussusception, initiated by a benign tumor, is occasionally seen and is the usual way that such tumors cause intestinal obstruction. Intussusception was caused by benign lesions in 3 cases, all of

lymphosarcoma in that abdominal pain was rare and that 3 patients with carcinoma complained only of the symptoms of secondary anemia. Newton and Buckley³ pointed out that anatomically identical adenocarcinomas of the small bowel can present the picture of intestinal obstruction or can only show

FIGURE 2 Lymphosarcoma of the Ileum

As shown by the photograph of the gross specimen, this lesion is larger and more diffuse than that of the carcinoma shown in Figure 1. The tumor was easily palpable preoperatively. The extent of the lesion is more apparent in the photograph taken after the lumen had been opened.

which had submucous lipomas. Otherwise, the benign tumors caused no symptoms. Rankin and Newell⁷ reported 35 cases of benign tumors of the small bowel, in 18 of which the lesion caused hemorrhage or intestinal obstruction.

The symptoms caused by malignant lesions in 30 cases are summarized in Table 2. The duration varied from a week to two years, with an average of about four months for lymphosarcoma and five months for adenocarcinoma. The patient with malignant argentaffinoma had had symptoms for two years. Adenocarcinoma differed clinically from

symptoms of secondary anemia without any gastrointestinal symptoms, although the lesion may be high in the jejunum. It is of further interest that a palpable abdominal mass was observed in only 2 patients with carcinoma. Intussusception may be initiated by adenocarcinoma^{9,10} but was not present in our series. Another important point in the history of patients with small-bowel carcinoma is that many have had barium roentgenologic studies of the stomach and colon, not once but several times, with negative findings and have therefore occasionally been told that they have a "nerv-

Benign Tumors

Theoretically, benign tumors should be demonstrable by x-ray examination as polypoid or smooth, round filling defects in the lumen of the intestine. Such findings are not too infrequent in the duodenum, and illustrations are readily found in the radiologic literature¹⁵⁻¹⁷. On the other hand, it is exceedingly rare to demonstrate benign tumors *per se* in the jejunum or ileum. Golden¹¹ states that he

in the terminal ileum and causes intussusception of the ileum into the cecum, the lesion can be demonstrated by barium enema (Fig 4). If there is intussusception of one loop of small intestine into another, this may be demonstrated by oral barium. Since the filling is from the proximal side, the x-ray picture is that of a narrow, barium-filled tract lying within a loop of small intestine. If some of the barium passes distally, a thin layer may outline the intussusceptum lying within the lumen of the

FIGURE 4 Intussusception of the Ileum into the Cecum Caused by a Lipoma of the Ileum

The film on the left, taken before evacuation, shows the filling defect in the cecum made by the invaginated ileum. The film on the right, taken after evacuation, shows the calculeae cornuities of the terminal ileum as cross striations within the lumen of the cecum and lower ascending colon.

has never been able to demonstrate a benign neoplasm in this way. A review of the literature shows only one report of such findings, in which the authors describe 3 cases.¹⁸ This infrequency is probably due to segmentation and overlapping of intestinal loops obscuring the lesions because of their small size and to the fact that the tumors rarely give rise to symptoms leading to x-ray investigation until they have caused intussusception.

The demonstration of this associated intussusception is the most frequent x-ray finding in benign tumors of the small intestine. If the tumor occurs

in the terminal ileum and causes intussusception of the ileum into the cecum, the lesion can be demonstrated by barium enema (Fig 4). If there is intussusception of one loop of small intestine into another, this may be demonstrated by oral barium. Since the filling is from the proximal side, the x-ray picture is that of a narrow, barium-filled tract lying within a loop of small intestine. If some of the barium passes distally, a thin layer may outline the intussusceptum lying within the lumen of the

Malignant Tumors

Carcinoma The x-ray findings in carcinoma of the small intestine vary with the type of tumor growth. The usual finding is an annular constriction with concave, shelf-like margins. Roentgenology frequently demonstrates only the proximal margin with a narrow rigid tract of barium, representing the constricted lumen through the tumor, extending from it. Occasionally, both the proximal

should first rule out lesions in the colon, stomach and duodenum by the usual methods of x-ray examination — that is, the barium enema and gastrointestinal series. These examinations not only serve to exclude lesions in the colon, stomach and duodenum but also may give the first clue of the presence of a neoplasm in the jejunum or ileum. For example, the barium enema may disclose the presence of intussusception of the ileum into the colon on the basis of a tumor of the terminal ileum. This point is discussed in more detail below.

X-ray examination may also disclose segments of small intestine filled with air, fluid or barium that, in view of the symptoms, should immediately arouse suspicion of a tumor and lead to further investigation. At this hospital, the routine gastrointestinal series includes the giving of a barium motor meal six hours before the fluoroscopic examination. If, at the time of fluoroscopy, the barium meal demonstrates a dilated segment of jejunum or ileum or shows almost complete retention of the barium in the stomach, with no demonstrable point of obstruction proximal to the ligament of Treitz, obstruction beyond this point should be sought.

Occasionally, unrelated x-ray examinations give the first indication of a small-bowel lesion. In 1 case cholecystograms revealed several dilated, fluid-filled loops of small intestine faintly outlined by unabsorbed Priodax retained in the loops. Follow-up barium studies disclosed a jejunal tumor. The valuable role of plain films of the abdomen in disclosing distended air-filled intestinal loops indicating ileus or obstruction is well known and needs no further mention.^{11, 12}

If, in the presence of intestinal symptoms, the gastrointestinal series and barium enema disclose no disease, more intensive study of the small intestine by special technics is indicated. In general, there are three methods available to the roentgenologist.

Motility series. This procedure is employed at various clinics under different designations and with minor variations in details of technic. The method used at this hospital is as follows. Thirty grams of barium sulfate in water is given at 8 o'clock on the morning of the examination, all food and fluids having been withheld from the patient since the previous evening. Half an hour after the ingestion of the barium, a film is taken, and this is repeated at intervals of half an hour to an hour. Each film is inspected by the roentgenologist immediately after processing, and if any abnormal segments of intestine are seen, the patient is fluoroscoped and spot films are taken as indicated. The examination is completed after the head of the barium column has reached the cecum and the terminal ileum has been well visualized. In this way the progress of the

barium through the entire jejunum and ileum can be followed.

Small-bowel enema. An alternative method of examination is the small-bowel enema, as described by Schatzki.¹³ This procedure consists of the passage of a Levine or Miller-Abbott tube into the duodenum so that its tip lies in the second portion. Under fluoroscopic observation, the entire small intestine is filled with a barium suspension that is allowed to run in through the tube in a slow uninterrupted flow. Spot films are taken during the examination as indicated.

The two methods outlined above may be used even in the presence of a partially obstructing lesion without danger of completing the obstruction, since the fluid state of the barium suspension is preserved in the ileum and jejunum and since there is no dehydrating action. Golden¹⁴ states that no evidence of damage was observed after the administration of barium by mouth in the presence of disease of the small intestine, even with narrow constrictions. One of our patients offered excellent proof of this opinion. The operative specimen showed a markedly constricting carcinoma of the jejunum through which air could be forced only with difficulty, and yet a few days prior to operation, barium administered by mouth passed readily through this area to the cecum with only slight delay proximal to it and with no evidence of a deleterious effect or barium plug at operation.

If complete intestinal obstruction with ileus is present, the two methods described above should not be used because the amount of barium suspension necessary for the examination further distends already dilated loops and is difficult to withdraw through a tube with a narrow lumen. Furthermore the procedures do not yield satisfactory results because the overlapping dilated barium-filled loops of intestine obscure the lesion, the barium is diluted greatly in the obstructed loops, and motility is absent or diminished, causing stasis of the barium proximal to the lesion. If it is desired to demonstrate the cause of an obstruction, the following method may be used.

Modified small-bowel enema. A Miller-Abbott tube is passed into the intestine, usually as a therapeutic measure when the patient is first seen. After the tube has reached the point of maximum progress and the dilated loops have been decompressed by suction, a small amount of thin barium suspension (35 to 40 cc) is introduced through the tube just proximal to the obstruction and under fluoroscopic observation the area of obstruction is examined.¹⁴ In this way much valuable information may be gained, and frequently the exact nature of the lesion demonstrated.

highly suggestive sign of these tumors. Recently, we saw in consultation the x-ray studies of a patient who was found to have an argentaffinoma involving the terminal ileum. The films showed a fairly smooth narrow segment of intestine about 10 cm in length and with the diameter of an ordinary lead pencil. It was concave, as if stretched around a soft-tissue mass. The mucosa through the segment appeared intact but was distorted, having a fine granu-

Swenson²² described a generalized lymphosarcomatous involvement of the small intestine in which x-ray examination showed a patchy irregular distribution of barium through the jejunum and upper ileum, with coarse irregular wall markings widely separated. Hypomotility was present. The picture resembled that seen in nutritional disturbances, such as sprue. Tannhauser and Davison²³ also described a case of the generalized form of

FIGURE 6 Carcinoma of the Jejunum

This tumor had produced intestinal obstruction. All the barium lies in the dilated intestinal loops proximal to the lesion, which is not outlined. The roentgenogram illustrates the "closed accordion" appearance of the dilated proximal loops, with the valvulae conniventes lying closely together.

lar appearance. There were no shelflike margins at the ends of the lesion. Fluoroscopically, it was reported to be fixed and rigid. The appearance was similar to that seen with long-standing chronic cicatrizing enteritis, or with involvement of a segment of intestine in an extrinsic chronic abscess of the peritoneal cavity.

Small benign nodular submucosal carcinoids should show, theoretically, smooth dome-shaped or polypoid filling defects projecting into the lumen, frequently multiple. No reports of the demonstration of such lesions could be found in the literature or in our own records. A carcinoid as the basis of an intussusception of the ileum into the cecum was reported by Brocher.²¹

Sarcoma. Lymphosarcoma is the most frequent sarcoma involving the small intestine. This involvement may be either localized or generalized

gastrointestinal pseudoleukemia in which there were numerous polypoid growths throughout the intestine showing as multiple small intraluminal filling defects on x-ray study. The localized form may present an x-ray appearance identical with that of carcinoma. As Doub and Jones²⁴ state, the tumors may be divided into three groups: the annular constricting lesions, which they consider rare in sarcoma; the subserous tumors, which show ulcerated and aneurysmal dilatations of the lumen of the involved segment; and those that present a polypoid intraluminal mass. In general it may be said that lymphosarcoma tends to involve a longer segment of intestine than carcinoma and less often causes marked constriction. The involved segment shows either an irregular lumen of normal or slightly less than normal caliber or actual dilatation and widening of the lumen owing to ulceration and necrosis.

and the distal concave margins with a constricted area between them may be shown, giving the typical napkin-ring appearance seen in annular carcinomas of the colon (Fig 5). The involved area is usually short, being less than 5 cm in length, rigid and often fixed. The mucosal pattern through it is destroyed. The lesion is more circumscribed in carcinoma than

ulceration within the tumor. The involved area is much longer than that seen with the annular type, all the reported lesions measuring several centimeters in length and the longest measuring 14 cm.

Frequently, the roentgenologist is able to demonstrate only the point of obstruction with dilated loops proximal to it, his interpretation must then be

FIGURE 5 Adenocarcinoma of the Jejunum

The roentgenogram on the left, an area of the plain film made during fluoroscopy, shows the constricting lesion with the characteristic biconcave shelf formation at either end. The roentgenogram on the right is of the specimen removed at operation which was clamped at both ends and filled with air. It is apparent that the annular constricting lesion almost completely obliterated the lumen. This is the case illustrated in Figure 1.

in lymphosarcoma. Proximal to the lesion the intestine is frequently dilated and may show accordion-like pleating of the valvulae conniventes of the portion just adjacent to the tumor (Fig 6). This is the probable result of contractile shortening of the longitudinal muscles of the intestinal wall in an attempt to overcome the obstruction. Intraluminal proliferative polypoid carcinomas are rarer and show on x-ray examination an irregular filling defect projecting into the lumen. Golden¹¹ reports an infiltrating type of carcinoma of the terminal ileum much longer than that ordinarily seen, with irregular borders resembling an inflammatory type of lesion. The x-ray appearance of a group of carcinomas classified as nonobstructing and extraluminal has been described by Lingley.¹² These give the x-ray picture of a large, dilated, irregular, barium-filled segment of intestine associated with a palpable mass. This appearance is the result of extensive necrosis and

limited to an obstructing lesion of the small intestine of undetermined nature. Malignant, as well as benign, tumors may give rise to intussusception, with x-ray findings similar to those described above under benign tumors.

Argentaffinoma. The malignant variety of this lesion may cause an annular constriction, with an x-ray appearance that is indistinguishable from an annular carcinoma. Miller and Herrmann²⁰ point out that the intraluminal portion of a carcinoid that has undergone malignant change is frequently not large but that there is extension into the wall of the intestine and into the mesentery, with resultant kinking or knuckling of the intestine at the site of the tumor that produces obstruction, either partial or complete. They demonstrated these x-ray findings in 3 proved cases of carcinoid and concluded that the roentgenologic demonstration of a tumor at a point of kinking and partial obstruction is a

diagnosis The lesions may likewise be the basis of intussusception This is especially true of myosarcomas

TREATMENT

The treatment of choice is resection of the involved segment of bowel along with its adjacent mesentery and restoration of the continuity of the intestine In the jejunum and ileum, resection and end-to-end or side-to-side anastomosis is performed The duodenum, however, presents a more complicated technical problem because of its anatomic

and well four years after resection of the ileum for lymphosarcoma, when he was lost to follow-up One patient* is living and well six years after resection of a carcinoma of the jejunum A single patient with a recent case of carcinoma of the jejunum is living and well seven months postoperatively The obvious causes for these poor therapeutic results are the facts that the diagnosis is made late and that the tumors metastasize early via the lymphatic vessels

The 2 cases of intussusception caused by submucous lipomas of the small intestine were treated by resection and end-to-end anastomosis Both

position None of the lesions of the duodenum in our series were operable, but the logical attack on a malignant primary tumor of the duodenum is along the lines pointed out by Whipple²⁶ for resection of carcinoma of the head of the pancreas or the ampulla of Vater An excellent review of the types of operative procedures in this field is given by Orr.²⁷ X-ray therapy was given postoperatively to all patients with lymphosarcoma The radiosensitivity of these tumors is well known,^{28, 29} but the results are usually temporary and palliative

A summary of the surgical procedures in this series is given in Table 3 In only 2 patients with adenocarcinoma of the duodenum was the diagnosis apparent at the time of operation, and both lesions were inoperable In the other 2 cases in this group carcinoma was found incidentally on microscopical examination of the specimen removed at subtotal gastrectomy for duodenal ulcer One of these patients is living and well ten years after operation, and the other did not respond to follow-up query The malignant tumors of the jejunum and ileum were resectable in 14 of 24 cases, and in the remainder, an exploratory operation, alone or in combination with a palliative sidetracking procedure, was done Four patients had no operation

The survival period for the patients with malignant tumors of the jejunum and ileum was universally short The average survival of 22 patients who underwent operative procedures was eleven and a half months for adenocarcinoma and six months for lymphosarcoma There was no response to follow-up query in 3 cases, but 1 patient was living

and well five and fifteen years respectively after operation Excellent results should be achieved in benign lesions, provided that the complicating obstruction or hemorrhage is recognized before it becomes irreversible It should be remembered that benign lesions may be multiple, and the whole small bowel should be explored if the patient's condition warrants it

SUMMARY

Sixty-five cases of benign and malignant primary tumors of the duodenum, jejunum and ileum are reviewed In 33 the tumors were malignant 18 were adenocarcinomas, 13 were lymphosarcomas and 2 were invasive argentaffinomas

Thirty-three patients had symptoms caused by small-bowel tumors of which 30 were malignant tumors Only 3 benign tumors were the cause of symptoms, and in each case there was an associated intussusception

The ileum was the most frequent portion of the intestine involved, but 13 cases of adenocarcinoma occurred in the duodenum or jejunum

The symptoms of small-bowel tumor are those of obstruction or anemia following bleeding into the alimentary tract No characteristic clinical picture was presented

The diagnosis depends on thorough barium-contrast roentgenologic investigation of the small bowel in every patient with suggestive symptoms

*This is a patient of Dr. Robert Zollinger who studied her in this hospital but performed the operation at an outside hospital The case represents one of the longest survivals of carcinoma of the small intestine that we have been able to find

Lymphosarcoma is likelier to produce multiple lesions than carcinoma, and there is frequently an associated palpable mass. The involved area is usually more irregular than that of carcinoma.

Swenson²² states that x-ray examination frequently shows a longer segment to be involved than

on nonobstructing extraluminal malignant tumors. Lingley¹⁹ described 3 cases in which the sarcoma presented an x-ray appearance similar to that discussed above under carcinoma. This appearance is more frequently seen with sarcoma than with carcinoma. Sarcomas, like the other malignant tumors,

FIGURE 7 *Lymphosarcoma of the Terminal Ileum*

This roentgenogram shows irregularity of the involved ileum, with filling defects distal to the ileocecal valve, which indicate involvement of the cecum. The mucosa is destroyed throughout the area of the lesion. The caliber of the involved bowel is normal or only slightly constricted. Lymphosarcoma produces changes closely resembling inflammatory lesions.

is actually found at operation or autopsy. He believes that this is caused by mesenteric extension of the tumor, with blocking of the lymphatic vessels and disturbance of the autonomic nervous control causing distortion of the mucosa and the lumen beyond the actual limits of the tumor. In an article

may produce lesions that remarkably resemble cicatrizing enteritis on x-ray study, especially if they occur in the terminal ileum. Menne²⁵ reported such a case, and one of our cases presented this appearance (Fig 7). Associated involvement of the cecum seen with sarcomas may help in the differential

of the first four lumbar vertebrae. The tissues down to the transverse processes were then infiltrated with 1 per cent procaine, a 22-gauge, 7.5-cm needle being used. Particular attention was given to the muscle fascia and the periosteum of the transverse processes, because contact with these structures was invariably uncomfortable. Next, 20-gauge, 12.5-cm sympathetic-block needles were inserted through wheals perpendicular to the skin to make contact with the transverse processes. The needles were then withdrawn and redirected about 30° medialward and 30° cephalad, so as to pass above the transverse processes until the body of

swung into the frontal plane of the body and perpendicular to the midline. In this position, the needle lay almost flush with the skin of the supraclavicular area. On further introduction the tip impinged on bone either of the transverse process of the seventh cervical vertebra or the neck of the first rib or the body of the seventh cervical vertebra between these two points. Approximately 8 cc of 2 per cent procaine solution was then injected.

OBSERVATIONS

All patients treated showed definite improvement of the peripheral vascular system. Changes usually

the vertebra was touched. As soon as contact with the body had been made, the needle was further introduced so as to slide off the body of the vertebra and to be near the anterolateral surface of the body. After aspiration showed the needle not to be in a blood vessel, 6 cc of 2 per cent procaine was injected.

Stellate-ganglion block was performed by an anterolateral approach, similar to that of Volpitta.³ The midpoint of the clavicle on the side to be injected was located, and a skin wheal raised about 2 cm above this point. A 22-gauge, 7.5-cm needle was inserted through the skin wheal downward medially and posteriorly to make contact with the first rib. The needle was then withdrawn and

occurred within five or ten minutes after injection. Subjectively, many patients experienced a "hot foot," and stated, "I can't remember when my foot felt so good." The duration of this improved feeling following the first block was about three days. After subsequent blocks the improvement was progressively prolonged. In 8 cases after the third block there was subjective improvement for ten weeks. In Case 4 after the third block improvement lasted for four months (Table 1).

Objectively, all manifestations of vasospasm disappeared within twenty minutes after procaine injection. Color changes occurred early and were closely followed by a rise in temperature, the transition from a cold cyanotic extremity to a warm pink

unless a satisfactory cause is found in the stomach or colon

The indications and methods of roentgenologic investigation are described in detail

The treatment of choice is radical surgery, but the results of such therapy in malignant small-bowel tumors are poor

Earlier diagnosis is the only way in which the results of treatment can be improved, and that depends on the more frequent examination by barium-contrast roentgenologic studies of the small bowel

VASOMOTOR DISTURBANCES IN POLIOMYELITIS, WITH SPECIAL REFERENCE TO TREATMENT WITH PARAVERTEBRAL SYMPATHETIC BLOCK

MAJOR VINCENT J COLLINS, MC, AUS,* FIRST LIEUTENANT WILLIAM L FOSTER, MC, AUS,† AND CAPTAIN WILLIAM J WEST, MC, AUS‡

HOT SPRINGS, ARKANSAS

POLIOMYELITIS in adults can no longer be considered unusual Lewin¹ states that the incidence is definitely increasing in the older age groups At the Army and Navy General Hospital, Hot Springs, Arkansas, a center for poliomyelitis patients, 131 cases in military personnel were studied Practically all the cases were convalescent—that is, the acute symptoms had subsided and the patients were observed prior to the end of the two-year interval arbitrarily set as the convalescent period

In a review of these cases vasomotor and sudomotor disturbances frequently appeared in the extremities These changes formed an important part of the symptomatology and consisted of varying degrees of cyanosis or discoloration of the skin, accompanied by mild to severe edema and hyperhidrosis The most frequent indications of vasomotor disturbances were coldness and sweating of the part involved

In an attempt to alleviate these distressing symptoms complicating poliomyelitis, paravertebral sympathetic blocks were performed, the results in 17 cases are reported below

TECHNIC

Patients scheduled for sympathetic block were premedicated with 0.2 gm of sodium amytal ninety minutes prior to nerve block and with a small dose of morphine and scopolamine one hour prior to nerve block Lumbar paravertebral sympathetic block was performed on patients with involvement of the lower extremities, and stellate-ganglion block on those with involvement of the upper extremities

The technic of lumbar sympathetic block employed was essentially that of Ochsner and DeBakey.² Patients were placed in the lateral recumbent position, for purposes of comparison, only one side was given a course of injections at a time The landmarks employed were the spinous processes, the transverse processes and the bodies of the lumbar vertebrae Skin wheals were raised 4 to 6 cm lateral to the upper part of the spinous processes

that 21 of 158 cases in New York had varying degrees of muscle spasm eight months after the acute illness. These workers also stated that they had no specific remedy for muscle spasm. In view of the results in 3 of our cases it seems probable that impulses producing pain and spasm are mediated in part by the sympathetic system and that relief can be obtained by sympathetic nerve blocks. It is also suggested that sympathetic blocks may relieve the pain, spasm and muscle tenderness in the acute phase of poliomyelitis as dramatically as it did in our 2 cases in the convalescent stage and 1 case in the acute stage. Therefore, with this report as a background, it is hoped that further investigations will be carried out to determine the status of sympathetic blocks and their efficacy in poliomyelitis.

SUMMARY

Vasomotor disturbances, such as edema, hyperhidrosis, coldness and chilblains, are frequently encountered in the convalescent period of poliomyelitis.

Sympathetic nerve blocks were employed to alleviate these distressing manifestations of disturbed vasomotor activity with partial to complete relief in 15 cases.

Pain, muscle spasm and muscle tenderness were completely relieved in 3 cases by sympathetic nerve blocks and without supplementary therapeutic measures, such as physiotherapy and hot packs.

It is suggested that the pain, tenderness and muscle spasm in the acute phase of poliomyelitis may also be alleviated by sympathetic blocks.

AN ERUPTIVE FEVER INVOLVING THE SKIN AND MUCOUS MEMBRANES (STEVENS-JOHNSON DISEASE)*

ARNALL PATZ, M D

BALTIMORE

IN 1866 von Hebra¹ first described erythema multiforme as a generalized skin eruption without marked systemic symptoms, a rare type with fever, malaise, prostration and an accompanying severe stomatitis and purulent conjunctivitis was mentioned. Kaposi,² in 1893, described an infrequent form with involvement of the mucous membranes. More recently, reports of erythema multiforme with occasional involvement of the mucous membranes of the eyes, mouth and genitalia have been presented.³⁻⁵

In 1922 Stevens and Johnson⁶ reported 2 cases of "a new eruptive fever associated with stomatitis and ophthalmia." They believed that the features of their cases, although previously described as a rare form of erythema multiforme, justified consideration as a separate entity. Many strikingly similar cases have subsequently been reported. The almost identical clinical pictures certainly merit recognition as a distinct syndrome. The name "Stevens-Johnson disease" has been used by many writers for this clinical entity.

The disease is usually characterized at the onset by mild conjunctivitis and stomatitis, which are followed in one or two days by fever, prostration

and a generalized erythematous skin rash that undergoes hemorrhagic or vesicular changes. By the end of the first week, the stomatitis becomes ulcerative or bullous, and the conjunctivitis severe, with a copious purulent discharge. Corneal ulceration with opacification or subsequent endophthalmitis is not infrequent. The usual period until resolution of the mucous-membrane lesions is two weeks. The skin lesions resolve in about three weeks. No known etiology of the disease has been established. Two fatal cases have been reported.

The following case is considered typical.

An 8-year-old boy of Italian descent was admitted to the hospital on May 15, 1945. Five days before admission an upper respiratory infection with burning, watery eyes and a sore throat had developed. On the following day the mouth became exquisitely tender and the upper lip swollen, with several small blisters; simultaneously, a discrete, purplish macular dime-sized lesion on the left forearm and an identical one on the abdomen were noted. Three days before admission the eyes became acutely inflamed and swollen. A physician found the temperature to be 102°F, and the patient was started on sulfadiazine. On the following day burning on urination and soreness about the glans penis were noted. Sulfadiazine was continued during the 3 days prior to admission. The temperature remained elevated between 101 and 102°F. The stomatitis, conjunctivitis, and balanitis became more intense, and on admission, the violaceous rash had become generalized. There was no history of the administration of other medications, including the sulfonamides. The past history revealed the usual childhood diseases.

*From the Medical and Pediatric Services, Sinai Hospital of Baltimore. Formerly, assistant resident in medicine, Sinai Hospital of Baltimore.

one was rapid and intense. Diminution in sweating occurred slowly, but a dry extremity was usually found within twenty minutes.

Edema cleared up slowly in all cases. Three patients remarked that on the day following their first sympathetic block they could get into a slipper easily. Generally, however, swelling diminished after the second block and continued thereafter. In Case 4 circumferential measurements of the left ankle showed a change from 33.6 cm. before the first block to 28.5 cm. eighteen days later. The right ankle diminished in size from 31.7 cm. to 27.3 cm. over a period of thirty days.
